vessels, were, as a rule, coming from *easterly* and passing in *westerly* directions. The entries show a great immigration of our ordinary autumn migrants from the east in the spring months, and on exactly the same lines and directions as are travelled by the same species in autumn. Had this movement been observed at one station only, we might perhaps have been induced to doubt the accuracy of the return, but the fact of five light-vessels, having no communication with each other, reporting the same circumstances, proves the correctness of the observations. On the east coast of Scotland Mr. J. A. Harvie-Brown says that the autumn migration of 1883 was pronounced, culminating in a grand rush from October 28 to November 3. The heaviest rush of birds, as compared with other years, was observed at the Isle of May on October 13 and 14. This was with a south wind, although as a rule it is a south-east wind at that point which brings the greatest flights. In the autumn of 1882, on the east coast of Scotland, the bulk of immigrants are recorded at the southern stations; in 1883 these conditions were reversed, the bulk being recorded from northern stations. On the east coast of England, in 1883, birds appear to have been very equally distributed over the whole coast-line. It will be gathered from the General Report that the dates of the rushes on the east coast of Scotland were slightly later than those on the east coast of England, and that the migrations past the more northerly stations in Scotland were in proportion later than in the south, and also that the dates of the heaviest rushes on the east coast agree fairly with the dates from the west coast. From the coasts of Ireland Messrs. A. G. More and R. M. Barrington report a decided improvement in filling up the schedules, in some cases three or four being returned from the same station. Forty-two stations were supplied with schedules in the spring of 1883, and thirty-five in the autumn of the same year, returns coming in from thirty-four, one only failing. The number of migrants in the autumn seems to have been more than usual. A great rush of thrushes (including, probably, redwings), blackbirds, and starlings, took place at the south-eastern and southern stations between October 25 and November 2—dates which agree with the great rush on the east coast of England. The migration was particularly marked at the Tuskar Rock, off the Wexford coast, which is proving itself the best Irish station, and no doubt marks the line of the chief passage from the British coast. The bulk of the immigrants appear to arrive on the south-eastern coast of Ireland, excepting such birds as the bernicle-goose and snow-bunting, which are mainly recorded from north-western stations, and rarely entered in schedules from the east or south coast. An interesting feature this year is the occurrence of several examples of the Greenland falcon on the west coast, no less than eight having been shot at various points from Donegal to Cork, and one Iceland falcon at Westport. Independent of the ordinary notes on migration, the general remarks of the light-keepers with reference to the nesting of sea-fowl on the islands or outlying skerries are of great interest, and no matter what results are arrived at from this special inquiry, it is satisfactory to be in correspondence with such a number of observers at isolated spots around the coast, and the information supplied cannot fail to be of much interest to future compilers. An interesting feature of the autumn migration is the occurrence of a flight of the blue-throated warbler (*Cyanecula suecica*). A single adult with bright-blue breast was observed at the Isle of May on the night of September 2–3. On the east coast of England twelve were obtained, all being birds of the year, and of these nine on the coast of Norfolk, besides about twenty others seen by competent observers. Very few goldcrests, compared with the enormous flights of the previous autumn, have appeared, and the same scarcity is observable in the Heligoland returns. Curiously enough, the hedge-sparrow (*Accentor modularis*), which migrated in immense numbers in the same autumn, has been almost entirely absent. About half a dozen are recorded at Heligoland, none on the east coast of England. Of the enormous immigration which crosses our east coast in the autumn, either to winter in these islands or merely on passage across them, a small proportion only appear to return by the same routes. Spring returns from lighthouses and light-vessels show that birds then move on the same lines as in the autumn, but in the reverse direction. These return travellers do not, however, represent anything like a tithe of the visible immigrants which, week after week and month by month, in the autumn, move in one broad stream on to the east coast. What is called the "first flight" of the woodcock arrived on the Yorkshire, Lincolnshire, and Norfolk coasts on the night of October 21. The "great flight," or rush, which covered the whole of the east coast from the Farne Islands to Yarmouth was on the nights of the 28th and 29th. These two periods correlate with the principal flights of woodcock across Heligoland. But few woodcock were recorded from stations on the east coast of Scotland, although at the Bell Rock Lighthouse, on the night from October 31 to November 1, Mr. Jack reports an enormous rush of various species, commencing at 7 p.m. Immense numbers were killed, pitching into the sea. "What we thought were woodcocks struck with great force; birds continued flying within the influence of the rays of light till the first streak of day, continually striking hard all night; we believe a great number of woodcocks struck and fell into the sea." Mr. Harvie-Brown records a very great spring migration of woodcock which appear to have crossed Scotland between the Clyde and the Forth on March 9, 10, 11, and 12, 1884. These were observed to be the small red Scandinavian bird, which are quite unmistakable and distinct from British-bred birds. The occurrence of *Locustella fluviatilis* at the Stevns Lighthouse at the entrance of the Oresund in Zealand is interesting, as it is the first recorded Danish example of this species. Altogether there has been a very marked absence on our British coasts of rare and casual visitants. The roller (*Coracias garrula*) occurred in October in two localities—one in Lincolnshire, the other in Suffolk. Two examples of the sooty shearwater (*Puffinus griseus*) were obtained in Bridlington Bay about the end of September. The island of Heligoland retains its pre-eminence as the casual resting-place of rare wanderers from other lands; and Mr. Gätke's list for 1883 includes *Turdus varius*, *Pratincola rubicola*, var. *indica*, *Phylloscopus superciliosus*, *Hypolais pallida*, *Motacilla citreola*, *Anthus cervinus*, *A. richardi*, *Oriolus galbula*, *Lanius major*, *Muscicapa parva*, *Linota exilipes*, *Emberiza melanocephala*, *E. cirlus*, *E. rustica*, *E. pusilla*, *Pastor roseus*, and *Xema sabinii*. It is well known that large numbers of European birds, presumably driven out of their course, are seen during the autumn migration far out over the Atlantic, alighting on the ocean-going steamers. It is proposed by Mr. Harvie-Brown to supply schedules to the principal lines of ocean steam-vessels for the better recording of these occurrences. It must be borne in mind that the immense and constantly-increasing traffic which in these days bridges the Atlantic and unites the Old and New Worlds, offers unusual chances for birds to break their flight, and ultimately, perhaps, to reach the American coast. In the comparatively narrow seas between the European continent and Great Britain birds are frequently noted as alighting on the rigging of vessels and lightships, roosting in the rigging during the night, to resume their flight at the first streak of dawn. It is a matter of congratulation that our American and Canadian fellow-workers have instituted a similar system of observation on the migration of birds. At the first Congress of the American Ornithologists' Union, held at New York City, September 26 to 28, 1883, a Committee on the Migration of Birds was appointed. It is intended to investigate this in all its bearings and to the fullest possible extent, not only in the accumulation of records of the times of arrival and departure of the different species, but to embrace the collection of all data that may aid in determining the causes which influence migration from season to season. Your Committee respectfully request their reappointment, and trust that the Association will enable them to continue the collection of facts.

Tenth Report of the Committee, consisting of Prof. E. Hull, the Rev. H. W. Crosskey, and Messrs. James Glaisher, H. Marten, E. B. Marten, G. H. Morton, W. Pengelly, James Plant, I. Roberts, Thos. S. Stooke, G. J. Symons, W. Topley, E. Wethered, W. Whitaker, and C. E. De Rance (Secretary and Reporter), appointed for the Purpose of Investigating the Circulation of Underground Waters in the Permeable Formations of England and Wales, and the Quantity and Character of the Water Supplied to Various Towns and Districts from those Formations. Drawn up by C. E. De Rance.—The Chairman and Secretary of your Committee are both unavoidably obliged to be absent from the Montreal meeting, which is a source of regret to themselves; the more so that, this being the case, it has been thought advisable to delay presenting their final Report on the Circulation of Underground Waters in South Britain until next year, when the Committee will have been twelve years in existence. During these years particulars have been collected

of the sections passed through by a very large number of wells and borings; a daily record has been obtained of the height at which water stands in many of these wells; investigations have been carried out as to the quantity of water held by a cubic foot of various rocks, by Mr. Wethered; and as to the filtering power of sandstones, and the influence of barometric pressure and lunar changes on the height of underground waters, by Mr. I. Roberts. During the present year the attention of the Committee has been directed to the remarkable influence of the earthquake which visited the East and East-Central Counties of England in March last, in raising the levels of the water in the wells of Colchester and elsewhere. More detailed information is still required as to the proportion of actual rainfall absorbed by various soils, over extended periods representing typical dry and wet years. Information on these heads and on other points of general interest bearing on the percolation of underground waters, referring to observations made in Canada or the United States, would be gladly welcomed by the Committee, and would be incorporated in their eleventh and final Report to be presented next year. Your Committee seek reappointment, but do not require a grant, as they have forms of inquiry on hand, and did not require to expend the whole of the grant of last year, a portion of which only has been drawn.

Appendix—Copy of Questions.—1. *Position* of well or shafts with which you are acquainted. 1*a*. State *date* at which the well or shaft was originally sunk. Has it been deepened since by sinking or boring? and when? 2. Approximate *height* of the surface of the ground above Ordnance Datum (mean sea-level). 3. *Depth* from the surface to bottom of shaft or well, with diameter. *Depth* from surface to bottom of bore-hole, with diameter. 3*a*. *Depth* from the surface to the horizontal drift-ways, if any. What is their length and number? 4. *Height* below the surface at which water stands *before* and *after* pumping. Number of hours elapsing before ordinary level is restored after pumping. 4*a*. *Height* below the surface at which the water stood when the well was first sunk, and height at which it stands now when not pumped. 5. *Quantity* capable of being pumped in gallons per day of twenty-four hours. Average quantity daily pumped. 6. Does the *water-level* vary at different seasons of the year, and to what extent? Has it diminished during the last ten years? 7. Is the ordinary *water-level* ever affected by local rains, and, if so, in how short a time? And how does it stand in regard to the level of the water in the neighbouring streams, or sea? 8. *Analysis* of the water, if any. Does the water possess any marked *peculiarity?* 9. *Section*, with nature of the rock passed through, including cover of Drift, if any, with *thickness*. 9*a*. In which of the above rocks were springs of water intercepted? 10. Does the cover of Drift over the rock contain *surface springs?* 11. If so, are these *land springs* kept entirely *out* of the well? 12. Are any large *faults* known to exist close to the well? 13. Were any *brine springs* passed through in making the well? 14. Are there any *salt springs* in the neighbourhood? 15. Have any wells or borings been discontinued in your neighbourhood in consequence of the water being more or less *brackish?* If so, please give section in reply to query No. 9. 16. Kindly give any further information you can.

PENDING PROBLEMS OF ASTRONOMY[1]

THIRTY-SIX years ago this very month, in this city, and near the place where we are now assembled, the American Association for the Advancement of Science was organised, and held its first meeting. Now, for the first time, it revisits its honoured birthplace.

Few of those present this evening were, I suppose, in attendance upon that first meeting. Here and there, among the members of the Association, I see, indeed, the venerable faces of one and another, who, at that time in the flush and vigour of early manhood, participated in its proceedings and discussions; and there are others, who, as boys or youths, looked on in silence, and listening to the words of Agassiz and Peirce, of Bache and Henry, and the Rogers brothers and their associates, drank in that inspiring love of truth and science which ever since has guided and impelled their lives. Probably enough, too, there may be among our hosts in the audience a few who remember that occasion, and were present as spectators.

[1] Address to the American Association for the Advancement of Science at Philadelphia, September 5, by Prof. C. A. Young, Professor of Astronomy at Princeton, retiring President of the Association. We are indebted to the courtesy of the editor of *Science* for an early copy of Prof. Young's address.

But, substantially, we who meet here to-day are a new generation, more numerous certainly, and in some respects unquestionably better equipped for our work, than our predecessors were, though we might not care to challenge comparisons as regards native ability, or clearness of insight, or lofty purpose.

And the face of science has greatly changed in the meantime; as much, perhaps, as this great city and the nation. One might almost say, that, since 1848, "all things have become new" in the scientific world. There is a new mathematics and a new astronomy, a new chemistry and a new electricity, a new geology and a new biology. Great voices have spoken, and have transformed the world of thought and research as much as the material products of science have altered the aspects of external life. The telegraph and dynamo-machine have not more changed the conditions of business and industry than the speculations of Darwin and Helmholtz and their compeers have affected those of philosophy and science.

But, although this return to our birthplace suggests retrospections and comparisons which might profitably occupy our attention for even a much longer time than this evening's session, I prefer, on the whole, to take a different course; looking forwards rather than backwards, and confining myself mainly to topics which lie along the pathway of my own line of work.

The voyager upon the Inland Sea of Japan sees continually rising before him new islands and mountains of that fairy-land. Some come out suddenly from behind nearer rocks or islets, which long concealed the greater things beyond; and some are veiled in clouds which give no hint of what they hide, until a breeze rolls back the curtain; some, and the greatest of them all, are first seen as the minutest specks upon the horizon, and grow slowly to their final grandeur. Even before they reach the horizon line, while yet invisible, they sometimes intimate their presence by signs in sky and air; so slight, indeed, that only the practised eye of the skilful sailor can detect them, though quite obvious to him.

Somewhat so, as we look forward into the future of a science, we see new problems and great subjects presenting themselves. Some are imminent and in the way,—they must be dealt with at once, before further progress can be made; others are more remotely interesting in various degrees; and some, as yet, are mere suggestions, almost too misty and indefinite for steady contemplation.

With your permission, I propose this evening to consider some of the pending problems of astronomy,—those which seem to be most pressing, and most urgently require solution as a condition of advance; and those which appear in themselves most interesting, or likely to be fruitful, from a philosophic point of view.

Taking first those that lie nearest, we have the questions which relate to the dimensions and figure of the earth, the uniformity of its diurnal rotation, and the constancy of its poles and axis.

I think the impression prevails that we already know the earth's dimensions with an accuracy even greater than that required by any *astronomical* demands. I certainly had that impression myself not long ago, and was a little startled on being told by the superintendent of our "Nautical Almanac" that the remaining uncertainty was still sufficient to produce serious embarrassment in the reduction and comparison of certain lunar observations. The length of the line joining, say, the Naval Observatory at Washington with the Royal Observatory at the Cape of Good Hope is doubtful—not to the extent of only a few hundred feet, as commonly supposed, but the uncertainty amounts to some thousands of feet, and may possibly be a mile or more, probably not less than a ten-thousandth of the whole distance; and the *direction* of the line is uncertain in about the same degree. Of course, on those portions of either continent which have been directly connected with each other by geodetic triangulations, no corresponding uncertainty obtains; and as time goes on, and these surveys are extended, the form and dimensions of each continuous land-surface will become more and more perfectly determined. But at present we have no satisfactory means of obtaining the desired accuracy in the relative position of places separated by oceans, so that they cannot be connected by chains of triangulation. Astronomical determinations of latitude and longitude do not meet the case; since, in the last analysis, they only give at any selected station the *direction of gravity* relative to the axis of the earth, and some fixed meridian plane, and do not furnish any *linear* measurement or dimension.

Of course, if the surface of the earth were an exact spheroid, and if there were no irregular attractions due to mountains and valleys and the varying density of strata, the difficulty could be

easily evaded; but, as the matter stands, it looks as if nothing short of a complete geodetic triangulation of the whole earth would ever answer the purpose,—a triangulation covering Asia and Africa, as well as Europe, and brought into America by way of Siberia and Behring's Straits.

It is indeed theoretically possible, and just conceivable, that the problem may some day be reversed, and that the geodesist may come to owe some of his most important data to the observers of the lunar motions. When the relative position of two or more remote observatories shall have been precisely determined by triangulation (for instance, Greenwich, Madras, and the Cape of Good Hope), and when, by improved methods, and observations made at these fundamental stations, the moon's position and motion relative to them shall have been determined with an accuracy much exceeding anything now attainable, then by similar observations, made simultaneously at any station in this hemisphere, it will be theoretically possible to determine the position of this station, and so, by way of the moon, to bridge the ocean, and ascertain how other stations are related to those which were taken as primary. I do not, of course, mean to imply that, in the *present state* of observational astronomy, any such procedure would lead to results of much value; but, before the Asiatic triangulation meets the American at Behring's Straits, it is not unlikely that the accuracy of lunar observations will be greatly increased.

The present uncertainty as to the earth's dimensions is not, however, a sensible embarrassment to astronomers, except in dealing with the moon, especially in attempting to employ observations made at remote and ocean-separated stations for the determination of her parallax.

As to the form of the earth, it seems pretty evident that before long it will be wise to give up further attempts to determine exactly what spheroid or ellipsoid *most nearly corresponds* to the actual figure of the earth, since every new continental survey will require a modification of the elements of this spheroid in order to take account of the new data. It will be better to assume some closely approximate spheroid *as a finality;* its elements to be for ever retained unchanged, while the deviations of the actual surface from this ideal standard will be the subject of continued investigation and measurement.

A more important and anxious question of the modern astronomer is, whether is the earth's rotation uniform, and, if not, in what way and to what extent does it vary? The importance, of course, lies in the fact that this rotation furnishes our fundamental measure and unit of time.

Up to a comparatively recent date, there has not been reason to suspect this unit of any variation sufficient to be detected by human observation. It has long been perceived, of course, that any changes in the earth's form or dimensions must alter the length of the day. The displacement of the surface or strata by earthquakes or by more gradual elevation and subsidence, the transportation of matter towards or from the equator by rivers or ocean-currents, the accumulation or removal of ice in the Polar regions or on mountain-tops,—any such causes must necessarily produce a real effect. So, also, must the friction of tides and trade-winds. But it has been supposed that these effects were so minute, and to such an extent mutually compensatory, as to be quite beyond the reach of observation; nor is it yet certain that they are not. All that can be said is, that it is now beginning to be *questionable* whether they are or are not.

The reason for suspecting perceptible variation in the earth's revolution, lies mainly in certain unexplained irregularities in the apparent motions of the moon. She alone, of all the heavenly bodies, changes her place in the sky so rapidly that minute inaccuracies of a second or two in the time of observation would lead to sensible discrepancies in the observed position: an error of one second, in the time, corresponding to about half a second in her place,—a quantity minute, certainly, but perfectly observable. No other heavenly body has an apparent movement anywhere nearly as rapid, excepting only the inner satellite of Mars; and this body is so minute that its accurate observation is impracticable, except with the largest telescopes, and at the times when Mars is unusually near the earth.

Now, of late, the motions of the moon have been very carefully investigated, both theoretically and observationally; and, in spite of everything, there remain discrepancies which defy explanation. We are compelled to admit one of three things,—either the lunar theory is in some degree mathematically incomplete, and fails to represent accurately the gravitational action of the earth and sun, and other known heavenly bodies, her movements; or some unknown force other than the gravitational attractions of these bodies is operating in the case; or else, finally, the earth's rotational motion is more or less irregular, and so affects the time-reckoning, and confounds prediction.

If the last is really the case, it is in some sense a most discouraging fact, necessarily putting a limit to the accuracy of all prediction, unless some other unchanging and convenient measure of time shall be found to replace the "day" and "second."

The question at once presents itself, How can the constancy of the day be tested? The lunar motions furnish grounds of suspicion, but nothing more; since it is at least as likely that the mathematical theory is minutely incorrect or incomplete as that the day is sensibly variable.

Up to the present time the most effective tests suggested are from the transits of Mercury and from the eclipses of Jupiter's satellites. On the whole, the result of Prof. Newcomb's elaborate and exhaustive investigation of all the observed transits, together with all the available eclipses and occultations of stars, tends rather to establish the sensible constancy of the day, and to make it pretty certain (to use his own language) that "inequalities in the lunar motions, not accounted for by the theory of gravitation, really exist, and in such a way that the mean motion of the moon between 1800 and 1875 was really less (*i.e.* slower) than between 1720 and 1800." Until lately, the observations of Jupiter's satellites have not been made with sufficient accuracy to be of any use in settling so delicate a question; but at present the observation of their eclipses is being carried on at Cambridge, Mass., and elsewhere, by methods that promise a great increase of accuracy over anything preceding. Of course, no *speedy* solution of the problem is possible through such observations, and their result will not be so free from mathematical complications as desirable,—complications arising from the mutual action of the satellites, and the ellipsoidal form of the planet. On account of its freedom from all sensible disturbances, the remote and lonely satellite of Neptune may possibly some time contribute useful data to the problem.

We have not time, and it lies outside my present scope, to discuss whether, and, if so, how, it may be possible to find a unit of time (and length) which shall be independent of the earth's conditions and dimensions (free from all *local considerations*), cosmical, and as applicable in the planetary system of the remotest star as in our own. At present we can postpone its consideration; but the time must unquestionably come when the accuracy of scientific observation will be so far increased that the irregularities of the earth's rotation, produced by the causes alluded to a few minutes ago, will protrude, and become intolerable. Then a new unit of time will have to be found for scientific purposes, founded, perhaps, as has been already suggested by many physicists, upon the vibrations or motion of light, or upon some other physical action which pervades the universe.

Another problem of terrestrial astronomy relates to the constancy of the position of the earth's axis in the globe. Just as displacements of matter upon the surface or in the interior of the earth would produce changes in the time of rotation, so also would they cause corresponding alterations in the position of the axis and in the places of the poles,—changes certainly very minute. The only question is, whether they are so minute as to defy detection. It is easy to see that any such displacements of the earth's axis will be indicated by changes in the *latitudes* of our observatories. If, for instance, the Pole were moved a hundred feet from its present position, towards the continent of Europe, the latitudes of European observatories would be increased about one second, while in Asia and America the effects would be trifling.

The only observational evidence of such movements of the Pole, which thus far amounts to anything, is found in the results obtained by Nyren in reducing the determinations of the latitude of Pulkowa, made with the great vertical circle, during the last twenty-five years. They seem to show a slow, steady diminution of the latitude of this Observatory, amounting to about a second in a century; as if the North Pole were drifting away, and increasing its distance from Pulkowa at the rate of about one foot a year.

The Greenwich and Paris observations do not show any such result; but they are not conclusive, on account of the difference of longitude, to say nothing of their inferior precision. The question is certainly a doubtful one; but it is considered of so

similar instruments, in the same manner, and reduced by the same methods and formulæ. So far as possible, the same observers are to be retained through a series of years, and are frequently to change stations when practicable, so as to eliminate personal equations. The main difficulty of the problem lies, of course, in the minuteness of the effect to be detected; and the only hope of success lies in the most scrupulous care and precision in all the operations involved.

Other problems, relating to the rigidity of the earth and its internal constitution and temperature, have, indeed, astronomical bearings, and may be reached to some extent by astronomical methods and considerations; but they lie on the border of our science, and time forbids anything more than their mere mention here.

If we consider, next, the problems set us by the moon, we find them numerous, important, and difficult. A portion of them are purely mathematical, relating to her orbital motion; while others are physical, and have to do with her surface, atmosphere, heat, &c.

As has been already intimated, the lunar theory is not in a satisfactory state. I do not mean, of course, that the moon's deviations from the predicted path are gross and palpable,—such, for instance, as could be perceived by the unaided eye (this I say for the benefit of those who otherwise might not understand how small a matter sets astronomers grumbling),—but they are large enough to be easily observable, and even obtrusive, amounting to several seconds of arc, or miles of space. As we have seen, the attempt to account for them by the irregularity of the earth's rotation has apparently failed; and we are driven to the conclusion, either that other forces than gravitation are operative upon the lunar motions, or else (what is far more probable, considering the past history of theoretical astronomy) that the mathematical theory is somewhere at fault.

To one looking at the matter a little from the outside, it seems as if that which is most needed just now, in order to secure the advance of science in many directions, is a new, more comprehensive, and more manageable solution of the fundamental equations of motion under attraction. Far be it from me to cry out against those mathematicians who delight themselves in transcendental and *n*-dimensional space, and revel in the theory of numbers,—we all know how unexpectedly discoveries and new ideas belonging to one field of science find use and application in widely different regions,—but I own I feel much more interest in the study of the theory of functions and differential equations, and expect more aid for astronomy from it.

The problem of any number of bodies, moving under their mutual attraction, according to the Newtonian laws, stands, from a physical point of view, on precisely the same footing as that of *two* bodies. Given the masses, and the positions and velocities corresponding to any moment of time, then the whole configuration of the system for all time, past and future (abstracting outside forces, of course), is absolutely determinate, and amenable to calculation. But while, in the case of *two* bodies, the calculation is easy and feasible, by methods known for two hundred years, our analysis has not yet mastered the general problem for more than two. In special instances, by computations, tedious, indirect, and approximate, we can, indeed, carry our predictions forward over long periods, or indicate past conditions with any required degree of accuracy; but a general and universally practicable solution is yet wanting. The difficulties in the way are purely mathematical: a step needs to be taken, corresponding in importance to the introduction of the circular functions into trigonometry, the invention of logarithms, or the discovery of the calculus. The problem confronts the astronomer on a hundred different roads; and, until it is overcome, progress in these directions must be slow and painful. One could not truly say, perhaps, that the lunar theory must, in the meanwhile, remain quite at a standstill: labour expended in the old ways, upon the extension and development of existing methods, may not be fruitless, and may, perhaps, after a while, effect the reconcilement of prediction and observation far beyond the present limits of accuracy. But if we only had the mathematical powers we long for, then progress would be as by wings: we should fly, where now we crawl.

simply *reflected* sunlight and sun-heat, and that the temperature of the lunar surface nowhere rises as high as the freezing-point of water, or even of mercury. At the same time, some astronomers of reputation are not disposed to admit such an upsetting of long-received ideas; and it is quite certain that, in the course of the next few years, the subject will be carefully and variously investigated.

Closely connected with this is the problem of a lunar atmosphere—if, indeed, she has any.

Then there is the very interesting discussion concerning changes upon the moon's surface. Considering the difference between our modern telescopes and those employed fifty or a hundred years ago, I think it still far from certain that the differences between the representations of earlier and later observers necessarily imply any real alterations. But they, no doubt, render it considerably *probable* that such alterations have occurred, and are still in progress; and they justify a persistent, careful, minute, and thorough study of the details of the lunar surface with powerful instruments: especially do they inculcate the value of large-scale photographs, which can be preserved for future comparison as unimpeachable witnesses.

I will not leave the moon without a word in respect to the remarkable speculations of Prof. George Darwin concerning the tidal evolution of our satellite. Without necessarily admitting all the numerical results as to her age and her past and future history, one may certainly say that he has given a most plausible and satisfactory explanation of the manner in which the present state of things might have come about through the operation of causes known and recognised, has opened a new field of research, and shown the way to new dominions. The introduction of the doctrine of the conservation of energy, as a means of establishing the conditions of motion and configuration in an astronomical system, is a very important step.

In the planetary system we meet, in the main, the same problems as those that relate to the moon, with a few cases of special interest.

For the most part, the accordance between theory and observation in the motions of the larger planets is as close as could be expected. The labours of Leverrier, Hill, Newcomb, and others, have so nearly cleared the field, that it seems likely that several decades will be needed to develop discrepancies sufficient to furnish any important corrections to our present tables. Leverrier himself, however, indicated one striking and significant exception to the general tractableness of the planets. Mercury, the nearest to the sun, and the one, therefore, which ought to be the best behaved of all, is rebellious to a certain extent: the perihelion of its orbit moves around the sun more rapidly than can be explained by the action of the other known planets. The evidence to this effect has been continually accumulating ever since Leverrier first announced the fact, some thirty years ago; and the recent investigation by Prof. Newcomb, of the whole series of observed transits, puts the thing beyond question. Leverrier's own belief (in which he died) was that the effect is due to an unknown planet or planets between Mercury and the sun; but, as things now stand, we think that any candid investigator must admit that the probability of the existence of any such body or bodies of considerable dimensions is vanishingly small. We do not forget the numerous instances of round spots seen on the solar disk, nor the eclipse-stars of Watson, Swift, Trouvelot, and others; but the demonstrated possibility of error or mistake in all these cases, and the tremendous array of negative evidence from the most trustworthy observers, with the best equipment and opportunity, makes it little short of certain that there is no Vulcan in the planetary system.

A ring of meteoric matter between the planet and the sun might account for the motion of the perihelion; but, as Newcomb has suggested, such a ring would also disturb the *nodes* of Mercury's orbit.

It has been surmised that the cause may be something in the distribution of matter within the solar globe, or some variation in gravitation from the exact law of the inverse square, or some supplementary electric or magnetic action of the sun, or some special effect of the solar radiation, sensible on account of the

planet's proximity, or something peculiar to the region in which the planet moves; but as yet no satisfactory explanation has been established.

Speaking of unknown planets, we are rather reluctantly obliged to admit that it is a part of our scientific duty as astronomers to continue to search for the remaining asteroids; at least, I suppose so, although the family has already become embarrassingly large. Still I think we are likely to learn as much about the constitution, genesis, and history of the solar system from these little flying rocks as from their larger relatives; and the theory of perturbations will be forced to rapid growth in dealing with the effects of Jupiter and Saturn upon their motions.

Nor is it unlikely that some day the searcher for these insignificant little vagabonds may be rewarded by the discovery of some great world, as yet unknown, slow moving in the outer desolation beyond the remotest of the present planetary family. Some configurations in certain cometary orbits, and some almost evanescent peculiarities in Neptune's motions, have been thought to point to the existence of such a world; and there is no evidence, nor even a presumption, against it.

Mercury as yet defies all our attempts to ascertain the length of its day, and the character and condition of its surface. Apparently the instruments and methods now at command are insufficient to cope with the difficulties of the problem; and it is not easy to say how it can be successfully attacked.

With Venus, the earth's twin sister, the state of things is a little better: we do already know, with some degree of approximation, her period of rotation; and the observations of the last few months bid fair, if followed up, to determine the position of her poles, and possibly to give us some knowledge of her mountains, continents, and seas.

It would be rash to say of Mars that we have reached the limit of possible knowledge as regards a planet's surface; but the main facts are now determined, and we have a rather surprising amount of supposed knowledge regarding its geography. By "supposed" I mean merely to insinuate a modest doubt whether some of the map-makers have not gone into a little more elaborate detail than the circumstances warrant. At any rate, while the "areographies" agree very well with each other in respect to the planet's more important features, they differ widely and irreconcilably in minor points.

As regards the physical features of the asteroids, we at present know practically nothing: the field is absolutely open. Whether it is worth anything may be a question; and yet, if one *could* reach it, I am persuaded that a knowledge of the substance, form, density, rotation, temperature, and other physical characteristics, of one of these little orphans would throw vivid light on the nature and behaviour of inter-planetary space, and would be of great use in establishing the physical theory of the solar system.

The planet Jupiter, lordliest of them all, still, as from the first, presents problems of the highest importance and interest. A sort of connecting-link between suns and planets, it seems as if, perhaps, we might find, in the beautiful and varied phenomena he exhibits, a kind of halfway house between familiar terrestrial facts and solar mysteries. It seems quite certain that no analogies drawn from the earth and the earth's atmosphere alone will explain the strange things seen upon his disk, some of which, especially the anomalous differences observed between the rotation periods derived from the observation of markings in different latitudes, are very similar to what we find upon the sun. "The great red spot" which has just disappeared, after challenging for several years our best endeavours to understand and explain it, still, I think, remains as much a mystery as ever,—a mystery probably hiding within itself the master-key to the constitution of the great orb of whose inmost nature it was an outward and most characteristic expression. The same characteristics are also probably manifested in other less conspicuous but equally curious and interesting markings on the varied and ever-changing countenance of this planet; so that, like the moon, it will well repay the most minute and assiduous study.

Its satellite system also deserves careful observation, especially in respect to the eclipses which occur; since we find in them a measure of the time required for light to cross the orbit of the earth, and so of the solar parallax, and also because, as has been already mentioned, they furnish a test of the constancy of the earth's rotation. The photometric method of observing these eclipses, first instituted by Prof. Pickering at Cambridge in 1878, and since re-invented by Cornu in Paris, has already much increased the precision of the results.

With reference to the mathematical theory of the motion of these satellites, the same remarks apply as to the planetary theory. As yet nothing appears in the problem to be beyond the power and scope of existing methods, when carried out with the necessary care and prolixity; but a new and more compendious method is most desirable.

The problems of Saturn are much the same as those of Jupiter, excepting that the surface and atmospheric phenomena are less striking, and more difficult of observation. But we have, in addition, the wonderful rings, unique in the heavens, the loveliest of all telescopic objects, the type and pattern, I suppose, of world-making, in actual progress before our eyes. There seems to be continually accumulating evidence from the observations of Struve, Dawes, Henry, and others, that these whirling clouds are changing in their dimensions and in the density of their different parts; and it is certainly the duty of every one who has a good telescope, a sharp eye, and a chastened imagination, to watch them carefully, and set down exactly what he sees. It may well be that even a few decades will develop most important and instructive phenomena in this gauzy girdle of old Chronos. Great care, however, is needed in order not to mistake fancies and illusions for solid facts. Not a few anomalous appearances have been described and commented on, which failed to be recognised by more cautious observers with less vivid imaginations, more trustworthy eyes, and better telescopes.

The outer planets, Uranus and Neptune, until recently, have defied all attempts to study their surface and physical characteristics. Their own motions and those of their satellites, have been well worked out; but it remains to discuss their rotation, topography, and atmospheric peculiarities. So remote are they, and so faintly illuminated, that the task seems almost hopeless; and yet, within the last year or two, some of our great telescopes have revealed faint and evanescent markings upon Uranus, which may in time lead to some further knowledge of that far-off relative. It may, perhaps, be that some great telescope of the future will give us some such views of Neptune as we now get of Jupiter.

There is a special reason for attempts to determine the rotation periods of the planets, in the fact that there is very possibly some connection between these periods on the one hand, and, on the other, the planets' distances from the sun, their diameters and masses. More than thirty years ago, Prof. Kirkwood supposed that he had discovered the relation in the analogy which bears his name. The materials for testing and establishing it were then, however, insufficient, and still remain so, leaving far too many of the data uncertain and arbitrary. Could such a relation be discovered, it could hardly fail to have a most important significance with respect to theories of the origin and development of the planetary system.

The great problem of the absolute dimensions of our system is, of course, commanded by the special problem of the solar parallax; and this remains a problem still. Constant errors of one kind or another, the origin of which is still obscure, seem to affect the different methods of solution. Thus, while experiments upon the velocity of light and heliometric measurements of the displacements of Mars among the stars agree remarkably in assigning a smaller parallax (and greater distance of the sun) than seems to be indicated by the observations of the late transits of Venus, and by methods founded on the lunar motions, on the other hand, the meridian observations of Mars all point to a larger parallax and smaller distance. While still disposed to put more confidence in the methods first named, I, for one, must admit that the margin of probable error seems to me to have been rather increased than diminished by the latest published results deduced from the transits. I do not feel so confident of the correctness of the value 8"·80 for the solar parallax as I did three years ago. In its very nature, this problem is one, however, that astronomers can never have done with. So fundamental is it, that the time will never come when they can properly give up the attempt to increase the precision of their determination, and to test the received value by every new method that may be found.

The problems presented by the sun alone might themselves well occupy more than the time at our disposal this evening. Its mass, dimensions, and motions, as a whole, are, indeed, pretty well determined and understood; but when we come to questions relating to its constitution, the cause and nature of the appearances presented upon its surface, the periodicity of its spots, its temperature, and the maintenance of its heat, the extent of its atmosphere, and the nature of the corona, we find the most radical differences of opinion.

The difficulties of all solar problems are, of course, greatly

enhanced by the enormous difference between solar conditions and the conditions attainable in our laboratories. We often reach, indeed, similarity sufficient to establish a bond of connection, and to afford a basis for speculation; but the dissimilarity remains so great as to render quantitative calculations unsafe, and make positive conclusions more or less insecure. We can pretty confidently infer the presence of iron and hydrogen and other elements in the sun by appearances which we can reproduce upon the earth; but we cannot safely apply empirical formulæ (like that of Dulong and Petit, for instance), deduced from terrestrial experiments, to determine solar temperatures: such a proceeding is an unsound and unwarrantable extrapolation, likely to lead to widely erroneous conclusions.

For my own part, I feel satisfied as to the substantial correctness of the generally received theory of the sun's constitution, which regards this body as a great ball of intensely heated vapours and gases, clothed outwardly with a coat of dazzling clouds formed by the condensation of the less volatile substances into drops and crystals like rain and snow. Yet it must be acknowledged that this hypothesis is called in question by high authorities, who maintain, with Kirchoff and Zöllner, that the visible photosphere is no mere layer of clouds, but either a solid crust, or a liquid ocean of molten metals; and there may be some who continue to hold the view of the elder Herschel (still quoted as authoritative in numerous school-books), that the central core of the sun is a solid and even habitable globe, having the outer surface of its atmosphere covered with a sheet of flame maintained by some action of the matter diffused in the space through which the system is rushing. We must admit that the question of the sun's constitution is not yet beyond debate.

And not only the constitution of the sun itself, but the nature and condition of the matter composing it, is open to question. Have we to do with iron and sodium and hydrogen as we know them on the earth, or are the solar substances in some different and more elemental state?

However confident many of us may be as to the general theory of the constitution of the sun, very few, I imagine, would maintain that the full explanation of sun-spots and their behaviour has yet been reached. We meet continually with phenomena, which, if not really contradictory to prevalent ideas, at least do not find in them an easy explanation.

So far as mere visual appearances are concerned, I think it must be conceded that the most natural conception is that of a dark chip or scale thrown up from beneath, like scum in a cauldron, and floating, partly submerged, in the blazing flames of the photosphere which overhang its edges, and bridge across it, and cover it with filmy veils, until at last it settles down again and disappears. It hardly *looks* like a mere hollow filled with cooler vapour, nor is its appearance that of a cyclone seen from above. But then, on the other hand, its spectrum under high dispersion is very peculiar, not at all that of a solid, heated slag, but it is made up of countless fine dark lines, packed almost in contact, showing, however, here and there, a bright line, or at least an interspace where the rank is broken by an interval wider than that which elsewhere separates the elementary lines,—a spectrum which, so far as I know, has not yet found an analogue in any laboratory experiment. It seems, however, to belong to the type of absorption spectra, and to indicate, as the accepted theory requires, that the spot is dark in consequence of *loss* of light, and not from any original defect of luminosity. Here, certainly, are problems that require solution.

The problem of the sun's peculiar rotation and equatorial acceleration appears to me a most important one, and still unsolved. Probably its solution depends in some way upon a correct understanding of the exchanges of matter going on between the interior and the surface of the fluid, cooling globe. It is a significant fact (already alluded to) that a similar relation appears to hold upon the disk of Jupiter, the bright spots near the equator of the planet completing their rotation about five minutes more quickly than the great red spot which was forty degrees from the equator. It is hardly necessary to say that an astronomer, watching our terrestrial clouds from some external station (on the moon, for instance), would observe just the reverse. Equatorial clouds would complete their revolution *more* slowly than those in our own latitude. *Our* storms travel towards the east, while the volcanic dust from Krakatoa moved swiftly west. We may at least conjecture that the difference between different planets somehow turns upon the question whether the body whose atmospheric currents we observe is receiving more heat from without than it is throwing off itself. Whatever may be the true explanation of this peculiarity in the motion of sun-spots, it will, when reached, probably carry with it the solution of many other mysteries, and will arbitrate conclusively between rival hypotheses.

The periodicity of the sun-spots suggests a number of important and interesting problems, relating, on the one hand, to its mysterious cause, and, on the other, to the possible effects of this periodicity upon the earth and its inhabitants. I am no "sun-spottist" myself, and am more than sceptical whether the terrestrial influence of sun-spots amounts to anything worth speaking of, except in the direction of magnetism. But all must concede, I think, that this is by no means yet demonstrated (it is not easy to prove a negative); and there certainly are facts and presumptions enough tending the other way to warrant more extended investigation of the subject. The investigation is embarrassed by the circumstance, pointed out by Dr. Gould, that the effects of sun-spot periodicity, if they exist at all (as he maintains they do), are likely to be quite different in different portions of the earth. The influence of changes in the amount of the solar radiation will, he says, be first and chiefly felt in alterations and deflections of the prevailing winds, thus varying the *distribution* of heat and rain upon the surface of the earth without necessarily much changing its *absolute amount*. In some regions it may, therefore, be warmer and drier during a sun-spot maximum, while in adjoining countries it is the reverse.

There can be no question that it is now one of the most important and pressing problems of observational astronomy to devise apparatus and methods delicate enough to enable the student to follow promptly and accurately the presumable changes in the daily, even the hourly, amounts of the solar radiation. It might, perhaps, be possible with existing instruments to obtain results of extreme value from observations kept up with persistence and scrupulous care for several years at the top of some rainless mountain, if such can be found; but the undertaking would be a difficult and serious affair, quite beyond any private means.

Related to this subject is the problem of the connection between the activity of the solar surface and magnetic disturbances on the earth,—a connection unquestionable as matter of fact, but at present unexplained as matter of theory. It may have something to do with the remarkable prominence of iron in the list of solar materials; or the explanation may, perhaps, be found in the mechanism by means of which the radiations of light and heat traverse inter-planetary space, presenting itself ultimately as a corollary of the perfected electro-magnetic theory of light.

The chromosphere and prominences present several problems of interest. One of the most fruitful of them relates to the spectroscopic phenomena at the base of the chromosphere, and especially to the strange differences in the behaviour of different spectrum-lines, which, according to terrestial observations, are due to the same material. Of two lines (of iron, for instance) side by side in the spectrum, one will glow and blaze, while the other will sulk in imperturbable darkness; one will be distorted and shattered, presumably by the swift motion of the iron vapour to which it is due, while the other stands stiff and straight.

Evidently there is some deep lying cause for such differences; and as yet no satisfactory explanation appears to me to have been reached, though much ingenious speculation has been expended upon it. Mr. Lockyer's bold and fertile hypothesis, already alluded to, that at solar and stellar temperatures our elements are decomposed into others more elemental yet, seems to have failed of demonstration thus far, and rather to have lost ground of late; and yet one is almost tempted to say, "It *ought* to be true," and to add that there is more than a possibility that its essential truth will be established some time in the future.

Probably all that can be safely said at present is, that the spectrum of a metallic vapour (iron, for instance, as before) depends not only upon the chemical element concerned, but also upon its physical conditions; so that, at different levels in the solar atmosphere, the spectrum of the iron will differ greatly as regards the relative conspicuousness of different lines; and so it will happen, that, whenever any mass of iron vapour is suffering disturbance, those lines only which particularly characterise the spectrum of iron in that special state will be distorted or reversed, while all their sisters will remain serene.

The problem of the solar corona is at present receiving much attention. The most recent investigations respecting it—those of Dr. Huggins and Prof. Hastings—tend in directions

which appear to be diametrically opposite. Dr. Huggins considers that he has succeeded in photographing the corona in full sunshine, and so in establishing its objective reality as an immense solar appendage, sub-permanent in form, and rotating with the globe to which it is attached. One may call it "an atmosphere," if the word is not to be too rigidly interpreted. I am bound to say that plates which he has obtained do really show just such appearances as would be produced by such a solar appendage, though they are very faint and ghost-like. I may add further, that, from a letter from Dr. Huggins, recently received, I learn that he has been prevented from obtaining any similar plates in England this summer by the atmospheric haze, but that Dr. Woods, who has been provided with a similar apparatus, and sent to the Riffelberg in Switzerland, writes that he has "an assured success."

Our American astronomer, on the other hand, at the last eclipse (in the Pacific Ocean), observed certain phenomena which seem to confirm a theory he had formulated some time ago, and to indicate that the lovely apparition is an apparition only, a purely optical effect due to the *diffraction* (not refraction, nor reflection either) of light at the edge of the moon—no more a solar appendage than a rainbow or a mock sun. There are mathematical considerations connected with the theory which may prove decisive when the paper of its ingenious and able proposer comes to be published in full. In the meantime it must be frankly conceded that the observations made by him are very awkward to explain on any other hypothesis.

Whatever may be the result, the investigation of the status and possible extent of a nebulous envelope around a sun or a star is unquestionably a problem of very great interest and importance. We shall be compelled, I believe, as in the case of comets, to recognise other forces than gravity, heat, and ordinary gaseous elasticity, as concerned in the phenomena. As regards the actual existence of an extensive gaseous envelope around the sun, I may add that other appearances than those seen at an eclipse seem to demonstrate it beyond question,—phenomena such as the original formation of clouds of incandescent hydrogen at high elevations, and the forms and motions of the loftiest prominences.

But of all solar problems, the one which excites the deepest and most general interest is that relating to the solar heat, its maintenance and its duration. For my own part, I find no fault with the solution proposed by Helmholtz, who accounts for it mainly by the slow contraction of the solar sphere. The only objection of much force is that it apparently limits the past duration of the solar system to a period not much exceeding some twenty millions of years, and many of our geological friends protest against so scanty an allowance. The same theory would give us, perhaps, half as much time for our remaining lifetime; but this is no objection, since I perceive no reason to doubt the final cessation of the sun's activity, and the consequent death of the system. But while this hypothesis seems fairly to meet the requirements of the case, and to be a necessary consequence of the best knowledge we can obtain as to the genesis of our system and the constitution of the sun itself, it must, of course, be conceded that it does not yet admit of any observational verification. No measurements within our power can test it, so far as we can see at present.

It may be admitted, too, that much can be said in favour of other theories; such as the one which attributes the solar heat to the impact of meteoric matter, and that other most interesting and ingenious theory of the late Sir William Siemens.

As regards the former, however, I see no escape from the conclusion, that, if it were exclusively true, the earth ought to be receiving, as was pointed out by the late Prof. Peirce, as much heat from meteors as from the sun. This would require the fall of a quantity of meteoric matter, more than sixty million times as much as the best estimates make our present supply, and such as could not escape the most casual observation, since it would amount to more than a hundred and fifty[1] tons a day on every square mile.

[1] In an article on astronomical collisions, published in the *North American Review* about a year ago, I wrongly stated the amount at fifty tons. There was some fatality connected with my calculations for that article. I gave the amount of heat due to the five hundred tons of meteoric matter which is supposed to fall daily on the earth with an average velocity of fifteen miles per second as fifty-three calories annually per square metre,—a quantity two thousand times too great. Probably the error would have been noticed if even the number given had not been so small, compared with the solar heat, as fully to justify my argument, which is only strengthened by the correction. I owe the correction to Prof. LeConte of California, who called my attention to the errors.

As regards the theory of Siemens, the matter has been, of late, so thoroughly discussed, that we probably need spend no time upon it here. To say nothing as to the difficulties connected with the establishment of such a far-reaching vortex as it demands, nor of the fact that the temperature of the sun's surface appears to be above that of the dissociation point of carbon compounds, and hence above their highest heat of combustion, it seems certainly demonstrated that matter of the necessary density could not exist in inter-planetary space without seriously affecting the planetary motions by its gravitating action as well as by its direct resistance; nor could the stellar radiations reach us, as they do, through a medium capable of taking up and utilising the rays of the sun in the way this theory supposes.

And yet I imagine that there is a very general sympathy with the feeling that led to the proposal of the theory,—an uncomfortable dissatisfaction with received theories, because they admit that the greater part of the sun's radiant energy is, speaking from a scientific point of view, simply wasted. Nothing like a millionth part of the sky, as seen from the sun, is occupied, so far as we can make out, by objects upon which its rays can fall: the rest is vacancy. If the sun sends out rays in all directions alike, not one of them in a million finds a target, or accomplishes any useful work, unless there is in space some medium to utilise the rays, or unknown worlds, of which we have no co nisance, beyond the stars.

Now, for my own part, I am very little troubled by accusations of wastefulness against Nature, or by demands for theories which will show what the human mind can recognise as "use" for all energy expended. Where I can perceive such use, I recognise it with reverence and gratitude, I hope; but the failure to recognise it in other cases creates in my mind no presumption against the wisdom of Nature, or against the correctness of an hypothesis otherwise satisfactory. It merely suggests human limitations and ignorance. How can one without sight understand what a telescope is good for?

At the same time, perhaps we assume with a little too much confidence that, in free space, radiation does take place equally in all directions. Of course, if the received views as to the nature and conduct of the hypothetical "ether" are correct, there is no possibility of questioning the assumption; but, as Sir John Herschel and others have pointed out, the properties which must be ascribed to this "ether," to fit it for its various functions, are so surprising and almost inconceivable, that one may be pardoned for some reserve in accepting it as a finality. At any rate, as a fact, the question is continually started (the idea has been brought out repeatedly, in some cases by men of real and recognised scientific and philosophic attainment), whether the constitution of things may not be such that radiation and transfer of energy can take place only between ponderable masses; and that, too, without the expenditure of energy upon the transmitting-agent (if such exist) along the line of transmission, even *in transitu*. If this were the case, then the sun would send out its energy only to planets and meteors and sister-stars, wasting none in empty space; and so its loss of heat would be enormously diminished, and the time-scale of the life of the planetary system would be correspondingly extended. So far as I know, no one has ever yet been able to indicate any kind of medium or mechanism by which vibrations, such as we know to constitute the radiant energy of light and heat, can be transmitted at all from sun to planet under such restrictions. Still one ought not to be too positive in assertions as to the real condition and occupancy of so-called vacant space. The "ether" is a good working hypothesis, but hardly more as yet.

I need not add that a most interesting and as yet inaccessible problem, connected with the preceding, is that of the mechanism of gravitation, and, indeed, of all forces that seem to act at a distance; as, for that matter, in the last analysis, *all* forces do. If there really be an "ether," then it would seem that somehow all attractions and repulsions of ponderable matter must be due to its action. Challis's investigations and conclusions as to the effect of hydrodynamic actions in such a medium do not seem to have commanded general acceptance; and the field still lies open for one who will show how gravitation and other forces can be correlated with each other through the ether.

Meteors and comets, seeming to belong neither to the solar system nor to the stellar universe, present a crowd of problems as difficult as they are interesting. Much has undoubtedly been gained during the last few decades; but in some respects that which has been learned has only deepened the mystery.

The problem of the origin of comets has been supposed to be solved to a certain extent by the researches of Schiaparelli, Heis,

'rof. Newton, and others, who consider them to be strangers oming in from outer space, sometimes "captured" by planets, nd forced into elliptic orbits, so as to become periodic in their notion. Certainly this theory has strong supports and great uthority, and probably it meets the conditions better than any ther yet proposed. But the objections are really great, if not nsuperable,—the fact that we have so few, if any, comets moving n hyperbolic orbits, as comets *met* by the sun would be expected o move; that there seems to be so little relation between the irection of the major axis of cometary orbits and the direction f the solar motion in space; and especially the fact, pointed out nd insisted upon by Mr. Proctor in a recent article, that the lteration of a comet's natural parabolic orbit to the observed lliptic one, by planetary action, implies a reduction of the omet's velocity greater than can be reasonably explained. If, r instance, Brorsen's comet (which has a mean distance from the n a little more than three times that of the earth) was really ce a parabolic comet, and was diverted into its present path the attraction of Jupiter, as generally admitted, it must have d its velocity reduced from about eleven miles a second to five. ow, it is very difficult, if not out of the question, to imagine y possible configuration of the two bodies and their orbits hich could result in so great a change. While I am by no eans prepared to indorse as conclusive all the reasoning in the ticle referred to, and should be very far from ready to accept e author's alternative theory (that the periodic comets have en ejected from the planets, and so are not their captives, but ir children), I still feel that the difficulty urged against the ceived theory is very real, and not to be evaded, though it may ossibly be overcome by future research.

Still more problematical is the constitution of these strange bjects of such enormous volume and inconceivable tenuity, selfminous and transparent, yet reflecting light, the seat of forces nd phenomena unparalleled in all our other experience. Hardly topic relating to their appearance and behaviour can be named which does not contain an unsolved problem. The varying ntensity, polarisation, and spectroscopic character of their light; he configurations of the nucleus and its surrounding nebulosity; nd especially the phenomena of jets, envelopes, and tail,—all emand careful observation and thorough discussion.

I think it may be regarded as certain that the explanation of hese phenomena when finally reached, if that time ever comes, vill carry with it, and be based upon, an enormous increase in ur knowledge as to the condition, contents, and temperature of nter-planetary space, and the behaviour of matter when reduced lowest terms of density and temperature.

Time forbids any adequate discussion of the numerous problems of stellar astronomy. One work, in its very nature incessant and interminable, consists, of course, in the continual bservation and cataloguing of the places of the stars, with ver-increasing precision. These star-places form the scaffold nd framework of all other astronomical investigations involving he motions of the heavenly bodies: they are the reference-points nd bench-marks of the universe. Ultimately, too, the comarison of catalogues of different dates will reveal the paths and notions of all the members of the starry host, and bring out the reat orbit of the sun and his attendant planets.

Meanwhile, micrometic observations are in order, upon the ndividual stars in different clusters, to ascertain the motions which occur in such a case; and the mathematician is called upon gain to solve the problem of such movement.

Now, too, since the recent work of Gill and Elkin in South frica, and of Struve, Hall, and others, elsewhere, upon stellar arallax, new hopes arise that we may soon come to some wider nowledge of the subject; that, instead of a dozen or so arallaxes of doubtful precision, we may get a hundred or more elating to stars of widely different brightness and motion, and be enabled to reach some trustworthy generalisations as to the onstitution and dimensions of the stellar universe, and the ctual rates of stellar and solar motion in space.

Most interesting, also, are the studies now so vigorously rosecuted by Prof. Pickering in this country, and many thers elsewhere, upon the brightness of the stars, and the connual variations in this brightness. Since 1875, stellar photometry as become almost a new science.

Then there are more than a myriad of double and multiple stars watch, and their orbits to be determined; and the nebulæ aim keen attention, since some of them appear to be changing form and brightness, and are likely to reveal to us some onderful secrets in the embryology of worlds.

Each star also presents a subject for spectroscopic study; for although, for the most part, the stars may be grouped into a very few classes from the spectroscopic point of view, yet, in detail, the spectra of objects belonging to the same group differ considerably and significantly, almost as much as human faces do.

For such investigations, new instruments are needed, of unexampled powers and accuracy, some for angular measurement, some for mere power of seeing. Photography comes continually more and more to the front; and the idea sometimes suggests itself that by and by the human eye will hardly be trusted any longer for observations of precision, but will be superseded by an honest, unprejudiced, and unimaginative plate and camera. The time is not yet, however, most certainly. Indeed, it can never come at all, as relates to certain observations; since the human eye and mind together integrate, so to speak, the impressions of many separate and selected moments into one general view, while the camera can only give a brutal copy of an unselected state of things, with all its atmospheric and other imperfections.

New methods are also needed, I think (they are unquestionably possible), for freeing time-observations from the errors of personal equation; and increased precision is demanded, and is being progressively attained, in the prevention or elimination of instrumental errors, due to differences of temperature, to mechanical strains, and to inaccuracies of construction. Astronomers are now coming to the investigation of quantities so minute that they would be completely masked by errors of observation that formerly were usual and tolerable. The science has reached a stage, where, as was indicated at the beginning of this address, it has to confront and deal with the possible unsteadiness of the earth's rotation, and the instability of its axis. The astronomer has now to reverse the old maxim of the courts: for him, and most emphatically at present, *De minimis curat lex*. Residuals and minute discrepancies are the seeds of future knowledge, and the very foundations of new laws.

And now, in closing this hurried and inadequate, but I fear rather tedious, review of the chief problems that are at present occupying the astronomer, what answer can we give to him who insists, *Cui bono?* and requires a reason for the enthusiasm that makes the votaries of our science so ardent and tireless in its pursuit? Evidently very few of the questions which have been presented have much to do directly with the material welfare of the human race. It may possibly turn out, perhaps, that the investigation of the solar radiation, and the behaviour of sun-spots, may lead to some better understanding of terrestrial meteorology, and so aid agricultural operations and navigation. I do not say it will be so,—in fact, I hardly expect it,—but I am not sure it will not. Possibly, too, some few other astronomical investigations may facilitate the determination of latitudes and longitudes, and so help exploration and commerce; but, with a few exceptions, it must be admitted that modern astronomical investigations have not the slightest immediate commercial value.

Now, I am not one of those who despise a scientific truth or principle because it admits of an available application to the affairs of what is called "practical life," and so is worth something to the community in dollars and cents: its commercial value is—just what it is—to be accepted gratefully.

Indirectly, however, almost all scientific truth has real commercial value, because "knowledge is power," and because (I quote it not irreverently) "the truth shall make you free,"—any truth, and to some extent; that is to say, the intelligent and intellectually cultivated will generally obtain a more comfortable livelihood, and do it more easily, than the stupid and the ignorant. Intelligence and brains are most powerful allies of strength and hands in the struggle for existence; and so, on purely economical grounds, all kinds of science are worthy of cultivation.

But I should be ashamed to rest on this lower ground: the highest value of scientific truth is not economic, but different and more noble; and, to a certain and great degree, its truest worth is more as an object of pursuit than of possession. The "practical life"—the eating and the drinking, the clothing and the sheltering—comes *first*, of course, and is the necessary foundation of anything higher; but it is not the whole or the best or the most of life. Apart from all spiritual and religious considerations, which lie on one side of our relations in this Association, there can be no need, before this audience, to plead the higher rank of the intellectual, æsthetic, and moral life above the material, or to argue that the pabulum of the mind is worth

as much as food for the body. Now, I am sure I can safely assert that, in the investigation and discovery of the secrets and mysteries of the heavens, the human intellect finds most invigorating exercise, and most nourishing and growth-making aliment. What other scientific facts and conceptions are more effective in producing a modest, sober, truthful, and ennobling estimate of man's just place in Nature, both of his puny insignificance, regarded as a physical object, and his towering spirit, in some sense comprehending the universe itself, and so akin to the divine?

A nation bound to the dust, and near to starving, needs first, most certainly, the trades and occupations that will feed and clothe it. When bodily comfort has been achieved, then higher needs and wants appear; and then science, for truth's own sake, comes to be loved and honoured along with poetry and art, leading men into a larger, higher, and nobler life.

SCIENTIFIC SERIALS

THE *Journal of the Franklin Institute* for July contains:—How to determine the grade of expansion and the size of a steam-engine which is to perform a given duty with the least total expenditure of money per working hour, by L. D'Auria.—Present state of the subject: "Heat of combustion of coal," by Chief Engineer Isherwood, U.S.N. (with figures and tables).—New York to Chicago in seventeen hours, by W. Barnet Le Van (4 diagrams).—Electro-dynamics, by John W. Nystrom.—A short paper criticising Moncel's formulæ in "Electricity as a Motive Power."—The ellipticity of planets, by Pliny Earle Chase, LL.D.—The discharge of turbine water-wheels, by J. P. Frizell (with tables).—The iridium industry, by Wm. L. Dudley (illustrated).—Physical and chemical tests of steel for boiler and ship plates for the U.S. Government cruisers, by Pedro G. Salom (5 pages of tables).—To tell iron from steel in small pieces (translated from Dingler's *Polytechnisches Journal*, by W. F. Worthington, U.S.N.—Report on the trial of the "City of Fall River," by J. E. Sague, M.E., and J. B. Adger, M.E.—Correspondence.—Book Notices.—Franklin Institute.—Items.—Low temperatures.—Ventilation of sewers.—Marsant's safety lamp.

Rivista Scientifico-Industriale, June and July.—Exposition of a new theory on the formation of hailstones; experiments on their artificial production, by Prof. Giovanni Luvini.—Remarks on radiant heat in connection with the second law of thermodynamics, by Prof. Adolfo Bartoli.—On the various hypotheses hitherto proposed to harmonise the results of the theory of radiation with the second law of thermodynamics, by the same author.—On Lambrecht's thermo-hygroscope, by the Editor.—Researches on the persistence of life and the vital functions i insects after decapitation, by Dante Roster.

Bulletin de l'Académie Royale de Belgique, June 7.—Obituary notice of M. F. Duprez, by M. Van der Mensbrugghe.—A contribution to the study of drinking-waters, and especially of those supplied to the city of Louvain, by M. Blas.—Researches on the germination of linseed and sweet almonds, by M. A. Jorissen.—On the Marine Station at Edinburgh, by MM. Van Beneden and Renard.—Note on a flint instrument discovered in the Quaternary alluvia of Hainaut in association with the remains of the mammoth, rhinoceros, and horse, by F. L. Cornet.—Discourse pronounced at the obsequies of M. Louis Hymans, by M. Wagener.—On gymnastic exercises in the Belgian educational establishments, by M. Vincent de Block.—On the poetical works of Jean d'Outremeuse, by M. Stanislas Bormans.

Archives des Sciences physiques et naturelles (*de Genève*), 3e periode, tomes ix. and x., 1883.—On electrolytic condensers, by C. E. Guillaume.—The determination of the absolute capacity of some condensers in electro-magnetic units, by M. Schneebeli.—On the theory of atmospheric absorption of solar radiation, by J. Maurer.—Note on cometary refraction, by G. Cellérier.—Researches on the absorption of ultra-violet rays by various bodies, by J. L. Soret.—Remarkable movements which sometimes follow the fall of hailstones and sleet, by D. Colladon.—Theory of dynamo-electric machinery, by R. Clausius.—Adjustment of resistance coils, by S. P. Thompson.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 8.—M. Rolland, President, in the chair.—The sitting was opened by the President with a few remarks on the ninety-ninth anniversary of M. Chevreul, *doyen* of the Academy.—Researches on the general development of vegetation in an annual plant (continued): nitrous elements and mineral constituents, by MM. Berthelot and André.—Note on the general resolution of the linear equation in matrices of any order, by Prof. Sylvester.—Remarks on balloon steering, by M. Duroy de Bruignac. The author considers that the experiment of August 9 at Chalais introduces a new phase of aërial navigation; and that the problem hitherto regarded as hopeless may soon be completely solved. It must, however, always remain of difficult application, the results depending on two essential conditions: that is, the necessity of increasing the propelling power and of diminishing the resistance of the air. A simple calculation shows that this resistance is in proportion to the cube of the sine in the angle of incidence of the prevailing atmospheric current. Hence for the small angles, which are rightly preferred, we get a variation of from 2° to 4° double or treble, or thereabouts, a tremendous obstacle, which has to be overcome.—Observations of the new Borelly planet 240, made at the Observatory of Algiers, by M. Ch. Trépied.—Observations of the solar spots and faculæ made at the Observatory of the Collegio Romano during the second quarter of the present year, by M. Tacchini.—A new contribution to the question of the origin of the phosphates of lime in the South-West of France, by M. Dieulafait. The author refers these formations to the action of saline waters during the Tertiary epoch, analogous to if not identical with those of the lagoons at the present time. The saline and concentrated waters of these lagoons, which certainly existed in Tertiary times, played a double part in the production of the natural phosphates of lime. In the first place they attacked the limestone rocks far more actively than ordinary water could have done; and then they contribute directly phosphoric acid, which is still being deposited in the shallow lagoons of the Rhone delta.—Experiments made for the purpose of testing the influence of pulps and other artificially prepared foods on cow's milk, by MM. A. Andouard and V. Dézaunay. These experiments, carried on during the years 1883 and 1884, tended to show that the prepared foods acted injuriously on the milk, but increased the quantity of butter without affecting its quality.—On the solar coronas recently observed in Switzerland, at Nice, and elsewhere, by M. L. Thollon. From a comparative study of the different accounts received of these phenomena, the author concludes that they are not merely halos, but true coronas, that is, an effect of diffraction produced either by fine dust or by light particles of moisture present in the elevated regions of the atmosphere.—Description of a meteor observed at the Trocadéro Observatory on the night of September 5, by M. L. Jaubert.

MODERN STEAM PRACTICE AND ENGINEERING

Modern Steam Practice and Engineering. By John G. Winton, assisted by W. J. Millar, C.E. (London: Blackie and Sons, 1883.)

THE want has long been felt by those employed in the engineering works of this country of a book which shall serve as a guide to the various operations in the workshop, giving a practical yet concise description of the various methods employed, and the reason for using any particular method. In some works we find the business conducted in an old-fashioned stereotyped way, and in others all the latest improvements are introduced. The number of workmen who can give the real reason for using any particular method is very small, the reason generally given being, "The work has always been done that way?" It is here where the apprentice finds one of the many difficulties he has to overcome; he can see the work done, but cannot fathom the reason for doing it any particular way; his foreman perhaps being too busy to help him, he has to do the best he can.

The volume before us will go a long way towards solving this difficulty. The author, being a practical man, treats the subject in a thoroughly practical way, using the technical language of the shops, thereby making the various descriptions and plates throughout the volume exceedingly clear. At the same time the higher principles involved in the various machines described are not overlooked, so that it is also a valuable book of reference in the drawing office, as well as a useful companion to those who have charge of men engaged in the various branches of mechanical engineering. For students attending the workshops and classes of the various engineering colleges it will be found to be very useful, giving as it does a *practical* description of the work, and helping considerably to get that knowledge which can alone be got in the workshops of the country.

The book is divided into five sections, subdivided into chapters.

Section I. is on the boiler and steam, commencing with a short chapter on coal and coal-mining. The author gives a short account of the troubles of the miner, and tells us of the methods in use for lining the shafts. Ventilation is dealt with; the various exhaust fans are next mentioned, with an illustration of the gimbal fan; then the author goes on to the usual methods for getting the coal. The chapter is a very appropriate commencement to the volume, although it gives a rather short account of the coal-mining industry.

We then come to a long chapter on stationary boilers, giving a good description of the various types in use. We miss the Lancashire boiler, with its two flues and conical water-tubes, from the illustrations. The author discusses the strength of riveted joints, giving the results of some experiments. We should have liked to find here a short account of the important researches on the strength of riveted joints carried out by Prof. Kennedy at the Engineering Schools of University College, London. The strength of cylindrical boilers is gone into fully, the various strains tending to rupture the plates are pointed out, and tables are given showing the proper thickness of plates for the different diameters. It is impossible here to give anything like a complete *résumé* of this chapter, no pains having been spared to get together as much information as possible; the author has succeeded in making it one of the most useful chapters in the work. He goes on to the foundations and settings for the different types of boiler, giving an account of the dimensions for the chimney. Smoke prevention is discussed, the conclusion at which the author arrives being thus stated: "We unhesitatingly give as our opinion that unless the attendant sees that the furnace is kept in proper trim, firing with the least quantity of coal, ofttimes replenished, all the refinements for the prevention of smoke will not attain the desired object, for careful firing is the main secret to arrive at."

Boilers for marine purposes are dealt with in a similar manner, the various types being discussed and illustrated. The arrangement of boilers for ships of war is gone into, high-pressure boilers having a fair share of the text. The proportions of marine boilers are treated, and suitable rules given for calculating the various dimensions, the chapter concluding with an illustration of the boilers of the s.s. *Parisian*, of the Allan Line of Atlantic steamers.

After showing the various methods for superheating and drying the steam by means of superheaters, both tubular and cylindrical, the author explains the methods of manufacture of boilers, more especially the best arrangement of plates and angle iron, and the staying of flat surfaces. We agree with the author when he says that this subject closely affects the interests of steam users, and the extract from a report of the National Boiler Insurance Company is well worth studying. Section I. concludes with the regulation and expansion of steam. The action of the slide valve is thoroughly explained, and the benefits derived from lap and lead pointed out. The different arrangements of the link motion are illustrated and clearly explained, then equilibrium slide valves are discussed and the arrangements clearly illustrated. The action of the indicator and the mode of driving the roller cylinder is shown; some very good examples of indicator diagrams taken from simple and compound engines are given; the section closing with a short chapter on the expansion of steam, with tables of hyperbolic logarithms, and the properties of saturated steam at different pressures.

Section II. is entirely devoted to stationary engines, commencing with the Cornish pumping-engine, afterwards dealing with the several different types of pumping-engines,—as pumping-engines for water-works, drainage works, and general purposes. The reader will here grasp the immense amount of trouble the author has taken to get all the information together, down to the smallest detail; each class of engine being well illustrated, its leading features pointed out, and the explanations of the different parts being very clear. Nor are the underground appliances overlooked, the pumps, valves and other parts in connection with the gear are thoroughly described and illustrated.

Pumping-engines for water-works are very similar

to those used for draining mines. We have several good examples; the description of the Tottenham pumping-engines is very interesting; and we have another example in the engines of the Berwick-on-Tweed Waterworks.

Of pumping-engines for drainage purposes, the London drainage system furnishes perhaps the best possible example; the Abbey Mills pumping-station with its eight engines giving an aggregate of 1140 horse-power, capable of dealing with 15,000 cubic feet of sewage per minute, lifting it 36 feet high; the Deptford pumping-station, with a horse-power of 500, lifting 10,000 cubic feet of sewage per minute to a height of 18 feet. The pumping-engines at Crossness are also described, having a collective horse-power of 500, dealing with 10,000 cubic feet of sewage per minute, with a varying lift of from 10 to 30 feet according to circumstances.

After a short account of an arrangement of centrifugal pumping machinery, the author deals with winding engines, giving a clear description of this class, and as an example we have a full-page engraving of an engine for the Benhar Coal Company, by Messrs. Gibb and Hogg, Airdrie.

The various types of blowing-engines are described; afterwards rolling-mill engines, having as examples some engines erected at the Dowlais Ironworks, and compound reversing rail-mill engines at the Hallside Steel-works, near Glasgow: these latter are shown in a full-page engraving and are fully described in the text.

Under water-pressure engines we find the accumulator and charging pumps illustrated, the hydraulic crane, and the usual hydraulic machinery for dock gates is described, the section concluding with an account of the hydraulic machinery for warehousing grain at the Liverpool Docks and a full-page engraving of hydraulic machine tools, designed by Mr. R. H. Tweddell.

In Section III. we have the marine engine thoroughly and completely explained. We here see what a tremendous advance has been made in the science of marine engine building, the engines of the latest additions to our mercantile navy being nearly theoretically perfect as far as the economical consumption of steam is concerned, and the proportions of the different parts more in accordance with the individual strains they have to withstand. The author treats the subject fully, each part and detail being illustrated, and reasons given for any peculiarity of construction in the engines described; he then goes on to screw propellers, and kindred appliances, the section concluding with a full-page engraving of the compound engines of the steam-ships *Servia* and *Parisian*, the descriptions being very clear and to the point. Rules for the horizontal marine engine finish the section.

Perhaps the locomotive engine, which is treated in Section IV., has advanced by greater strides than any other machine within the last twenty years, the reasons being that the traffic on the railways has got heavier, competition has forced the companies to run the trains at higher speeds, at the same time that the vehicles composing the trains have increased both in size and weight.

This increase means that the engine must have a higher tractive power, which can only be got by increasing the weight on the driving-wheels; larger cylinders must be used, and consequently a larger boiler and fire-box for the increased consumption of steam. As an example of an express passenger locomotive of the present day, we may take the engines designed by Mr. Stirling for the Great Northern Railway, having driving-wheels 8 feet in diameter, cylinders 18 inches in diameter with a stroke of 2 feet 4 inches. Compare these engines with one built fifteen or twenty years ago, and the marvellous change will be at once apparent.

The author commences the section with a variety of fire-boxes designed to consume the smoke when burning coal, some being very complicated. All locomotives of the present day burn coal, and from the very complicated fire-boxes illustrated, the fire-box has resolved itself into a perfectly plain box, having a brick arch, to mix the products of combustion previous to their passage through the tubes. This when fired properly is quite capable of consuming all the volatile hydrocarbons in the coal without the formation of any smoke.

The illustrations in the earlier part of the section are somewhat old-fashioned; the one showing the stays inside a locomotive boiler might have been of more recent design. We remember having seen a boiler of the same type on a locomotive built in 1847. With this as the only drawback, the section treats the subject in a clear and practical way; we do not know of any work in which one can find so much information.

In the description of the American locomotive, one finds many arrangements which look strange to those accustomed to English practice, but we cannot notice any peculiarity which we think could be adopted in this country with advantage. After a short account of the different classes of automatic continuous brakes, in which the Westinghouse and vacuum automatic brakes are discussed, we have some very good examples of the latest locomotive practice of this country. The engraving showing the vertical and horizontal sections of a bogie passenger engine, for the Caledonian Railway, is very clear, and the description good. Afterwards we find engines for the Great Northern, London and North-Western, and North British Railways thoroughly and clearly discussed, the general constructions being explained. The section concludes with a specification for a bogie locomotive, designed by Mr. William Kirtley for the London, Chatham, and Dover Railway, and a set of rules are compiled for the construction of locomotives.

In Section V. there is a very interesting and useful account of the construction of iron ships. The section of necessity treats the subject generally, the scope of iron shipbuilding being so large. The transverse and longitudinal methods of construction are explained, an account is given of the late Mr. William Froude's experiments with ship models, and as an example of recent practice we have the longitudinal section and deck plans of the s.s. *Orient*, with a concise description of her construction; afterwards the rigging is explained, with illustrations of the sparring and sail plan of a full-rigged ship. Then comes a short account of armoured war-ships, with a description of H.M.S. *Polyphemus*, the section concluding with dredgers, and examples of specifications for iron ships to Lloyd's rules.

Under the head of engineering works, the author gives a description of floating docks, the construction of iron roofs, the construction of, and strain on, wrought-iron

girders. There is a very clear analysis of the strains on the struts and ties in the lattice girder; the construction and sectional area of each strut and tie is worked out: next the suspension bridge is discussed, the general construction being explained.

The last few subjects treated in the volume include the fire-engine and gas-engine, with several other short accounts of the newest inventions, concluding with a chapter on the strength of materials.

In the publishers' preface we read that the present work is intended to furnish a reliable guide to practical engineers and others connected with the engine-shop and building-yard. This end has been most satisfactorily accomplished, and both authors and publishers may be congratulated on having placed before the public a most useful book; the printing is exceedingly clear, and the illustrations in the text good; the separate series of engraved plates add much to the value of the volume, without which many long descriptions would have been necessary. The book deserves a place in every technical library in the country. Those learning any branch of mechanical engineering will do well to study it, for it is one of the few really practical works published.

OUR BOOK SHELF

Catalogue and Handbook of the Archæological Collections in the Indian Museum. Part II. By John Anderson. (Calcutta.)

WE have already drawn attention to the first part of this excellent Catalogue, which thoroughly fulfils its promise of being not only an exhaustive list of the valuable objects in the Indian Museum, but a scholarly guide to them as well. The second part is occupied with Buddhist, Jain, Brahminical, and Mohammedan sculptures, and with the collections from Southern India, Persia, and other parts of the East. Appendixes have been added at the end of the book, including two by Prof. Warden and Mr. Growse. The work will be of great value to students of Indian archæology, and more especially to those who are devoting themselves to Buddhistic research. The Indian Museum is naturally a storehouse of antiquities throwing light on the past history of India and its relations with the West, and these have now been brought to the knowledge of scholars in a thoroughly satisfactory way.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Barnard's Comet

LAST night (September 22) this comet was well seen in the 3-foot telescope. It was large (at least 4′ over), brighter to the middle, but without nucleus; a position was measured from a faint star involved in the light of the head. At 8h. 20m. the position by circle reading was *a* 19h. 45m. 50s., and 117° 16′ 30″ N.P.D.

Ealing, September 23

The Krakatoa Eruption

BY this morning's post I have received, in a rather roundabout way from India, a translation of a Dutch account of the Krakatoa eruption, which, if you have not had it already, seems to contain some interesting variations on, or additions to, the mass of matter that you have already printed on that subject. Indeed the only postscript that could now be well added to it is the comfortable and encouraging discovery of the late French scientific expedition to the effect that the eruption is now positively over. The Batavians, as you are probably aware, feared that another eruption was preparing, in consequence of the immense number of stones still being ejected and clouds of smoke emitted. But the French *savants* discovered that no stones were being thrown up, only immense quantities of them tumbling down the mountain's sides; and this because the material, of which those new sides of the mountain are now composed, is so extraordinarily friable that the heat of the sun each day breaks them up, and the quiet force of gravitation brings the pieces galloping down the steep slopes, and plunging at last into the sea, to the danger of passing vessels,—but only by day, and when the sun is shining, for at night everything is quiet; and if by day and night a cloud forms above the mountain-top, it is neither smoke nor gaseous emanation, but merely the infinitely fine powdery matter of the broken-up and rolling stones of the day rising into the air and moving along with its currents up along the slopes which have been warmed by the sun.

C. PIAZZI-SMYTH

15, Royal Terrace, Edinburgh, September 15

The Sky-Glows

I WAS not aware before reading Mr. Leslie's letter in NATURE of the 11th inst. (p. 463) that any of the phenomena supposed to be connected with the volcanic dust had been seen before the eruption of Krakatoa in May 1883. Would the whole text of the description of those seen in February 1883 in Natal, from which Mr. Leslie gives a quotation, indicate them to be exactly similar to those seen since the great eruption? Where can a description of them be found?

The remarkable sunsets reported as seen in Mauritius after May 1883 and before the great eruption of Krakatoa, were by some attributed to the earlier volcanic disturbance, while others have expressed doubts whether they were really similar to those so generally noticed last autumn and winter.

It was not in the least the purpose of my former letter to imply the necessity of visiting a mountainous country to see the red corona round the sun; I am aware it is still plainly visible in England, and do not doubt even in London in fairly clear weather, having observed it when there in May last, not only within an hour of sunset or sunrise, but at all times of the day. But I wished to draw your readers' attention to the fact that this corona is much better seen in the clearer air at great altitudes, where also it is not necessary, as in England, that the sun be hidden by a cloud for it to be well seen.

I had not seen it stated before that the phenomena have been visible in England for years past. There is much more to be seen than a "blanching of the sun," as Mr. Leslie calls it, so that perhaps we are not both discussing the same phenomenon. Besides the bluish or greenish light immediately round the sun, which is not very striking, there is a broad red or brown band beyond, which is so. Has this been seen in England previous to last November? It has been habitual for me to scan the neighbourhood of the sun for halos during twenty-five years, and I never observed it previously to the date mentioned. It is true that the circumstances favourable for producing halos are unfavourable for seeing the red ring; nevertheless, since the latter first appeared in November I have not unfrequently seen it at the same time with a halo. It is also true that I saw portions of this red ring some days before I recognised them as a new phenomenon, but then they were only visible in gaps between clouds, so that I took them to be on thin cloud, and simply examples of the nacreous hues of thin films; any large extent of sky would probably have enabled me to perceive their true character. It is therefore very difficult for me to believe that the corona was visible in this country much, if at all, before last November.

Whether the phenomenon is ordinarily noticeable in volcanic countries I have not learnt; information from observers in such places would be of much value towards the elucidation of this interesting question. I gather from Prof. G. H. Stone's statement (NATURE, vol. xxix. p. 404) that a somewhat similar appearance is commonly visible in Colorado, where it may perhaps be attributed to the higher layers of dust of that very dusty region.

T. W. BACKHOUSE

Sunderland, September 20

THE glowing sunsets having reappeared, though far less brilliant than in November and December last, I send you a list of the most remarkable of them which have been noticed at Clairvaux, in the Department of Aube. They appeared with the same features as have been so often described in NATURE, and were especially glowing on the following days:—November 25, 27, 28; December 12; January 7, 12; August 6, 22 (feeble, sky not quite bright), and 23 (more brilliant); September 10 (feeble, bright sky, beautiful pink coloration in the east) and 17 (bright sky, bright pink coloration one hour after sunset). When the sky is bright, the rise of the moon is preceded, for nearly one hour, by a bright illumination of the sky.

Clairvaux, Aube P. K.

FOR the last four evenings, the 15th, 16th, 17th, and 18th, and again to-night, the colour of the sky from 20 to 25 minutes after sunset has taken that deep magenta glow looking very like the effect of a great fire, only lighter in tone. Last night, the 18th, this lasted until after 7 o'clock, and stars were then shining through it as they do through an aurora.

The reappearance of these glows was to be expected, as the haze and ruddy glow about the sun by day has, so far as I have been able to see, never really been long absent since attention was first drawn to it last autumn. I have now received a letter from Sydney, dated July 24, in which the writer says: "Since we have been in the Southern Hemisphere the sunsets have certainly had more striking colours, and on many occasions I have seen that peculiar magenta or mauve tint in the sky like aurora, only bluer in colour, while the sky has been very white just before sundown." The writer of the above is used to the look of the sun and sky, being an officer on board a mail steamer. I had suspected that absence of colour more or less in the sunsets here during our summer might be owing to the position of the sun rather than to any diminution in the quantity of vapour in the higher atmosphere, and had asked the writer of the above to note as he went south, in their winter, whether there was any increase in the colour of the after-glows, &c., being led to think this might be the case from reading the report of Mr. Neison, Director of the Natal Observatory, in which he speaks of having "first observed these phenomena in February 1883, from which time they increased in intensity until June, after which there was an interruption until the month of August." This led me to expect a return of strongly marked colour in our after-glows in autumn, increasing probably in intensity and duration during our winter months, when the weather is clear enough to see the sky. ROBT. LESLIE

Moira Place, Southampton, September 19

The Diffusion of Species

THE vast and altogether exceptional assemblage of Salpæ mentioned in NATURE (September 11, p. 462) by the Duke of Argyll as having been observed by him whilst recently cruising in the Hebridean seas, was due, in all probability, to the extension in a north-easterly direction of the ordinary surface-current of the Atlantic, or to an unusually long continuance of steady south-westerly wind, the effect of which would be to drive the superficial water of the Atlantic before it to the British coasts, and, with the water, the enormous multitudes of Salpæ which are occasionally to be met with in the latitude of the Canaries and Cape Verd Islands.[1]

During voyages to and from Bengal, *viâ* the Cape, in the good old days of sailing vessels, I repeatedly came across vast aggregations of these creatures, my attention having been specially called to them whilst engaged as I generally was for many hours by night as well as by day, in using a towing net from the stern ports for the capture of natural history specimens.

On my last voyage from Bengal in 1857 the ship sailed through some fifty or sixty miles of what the Duke aptly describes as Salpa soup, and which looked exactly like boiled tapioca. The quantity of Salpæ present in a bucket of the sea-water was, at least, equal in volume to the volume of water, but then the bodies of the Salpæ themselves consist in reality of more than 90 per cent. of water. On the occasion referred to, almost the entire mass consisted of a small species of Salpa about an inch in length, but nevertheless large enough to render the bright yellow digestive cavity of each, which is about the size of the smallest pin's head, distinctly visible. This was invariably full of certain species of oceanic diatoms the endochrome of which imparted the yellow colour. It is worthy of remark that in the case of the Salpæ, as well as many other organisms holding a yet lower position in the animal scale, there undoubtedly exists a selective power which enables them to pick out certain kinds of food in the midst of a superabundance of different kinds.

In the tropical Atlantic and Indian Oceans also I have seen, during calms, immense numbers (though not to be compared with the gatherings of the smaller Salpæ) of the larger chain Salpæ. These sometimes attain a length of from 8 to 10 inches, and have stomachs as large as a good-sized marble or hazel-nut.

But the most interesting assemblage of the lower forms of pelagic life was noticed by me about 200 miles from Ceylon, during a dead calm of four days' duration, when the sea was as smooth as a mirror, and undisturbed save by its never-ceasing majestic swell. Deep down, as far as the eye could penetrate, were to be seen numbers of brightly coloured water-snakes, delicately tinted "Venus's girdles," "Velellæ," and countless multitudes of those more minute living things which, though barely visible as mere specks to the unaided vision, are full of beauty and interest when observed under the microscope. Such a calm is a veritable pandemonium to the "skipper,"—to the naturalist it is a paradise. G. C. WALLICH

September 14

[1] As is well known, vast assemblages of Salpæ and kindred forms constantly occur at the surface in Arctic and Subarctic seas during the prevalence of moderate weather.

I AM specially interested in the Duke of Argyll's letter on the above subject (p. 462), being a resident during nearly half the year in the most southern of the Hebrides. His Grace is so competent a naturalist, and so accurate an observer, that I assume at once he had evidence which satisfied himself that an adder swam from Mull to Iona. Still I must be pardoned if I say that your readers have not been supplied with the proofs which have satisfied his Grace. A boy and girl in Iona, who, I presume, had never seen an adder in their lives, killed a creature in the sea there. Might it not have been an eel?

As regards distribution of species I may mention the following. In this island (Islay) we have multitudes of *stoats* but not a single *weasel*, while I am informed on trustworthy authority that in the neighbouring island of Colonsay there are many weasels but not a single stoat. R. SCOT SKIRVING

Sunderland House, Islay, September 18

Shifting of the Earth's Axis

IN the very interesting address of Prof. Young (NATURE, September 18, p. 501) he refers to the variability of the earth's axis, and states that a change of 1" per century has been detected at Pulkowa, but that "the Greenwich and Paris observations do not show any such result." Now only last year, in the "Pyramids and Temples of Gizeh," I had (p. 126) noted that the Greenwich observations *did* appear to show a change, and that a change of the same amount and same direction as is stated by Prof. Young for Pulkowa; the observations of this century showing a decrease of 1" of latitude per century, or with those of Maskelyne a decrease of 1"·38 per century.

This change I adduced as corroborating the result shown by four very accurate orientations of the earliest buildings, the Gizeh pyramids. These structures, whose errors are but a few seconds of angle, agree in standing as much as 4' or 5' to the west of the present north. This would imply a change of about 5" or 6" per century in the direction of long. 120°; a result quite comparable to the motion of 1" or 1"·4 per century in long. 0° and 30°. Such a change might be effected by causes which are beyond our observation; as, for instance, unbalanced ocean circulation equal to a ring of water only 4 square miles in section moving at a mile an hour across the poles. If this motion of 6" per century in long. 120° is still in action, we might now expect to find a change of about 5" in the meridian determined at the beginning of the Ordnance Survey, a ground of observation which should not be neglected. Salmon-Breeding

MR. FRANCIS DAY's interesting communication last week (p. 488) on this subject is likely to attract more attention from biologists and pisciculturists than any other recently-ascertained fact in the natural history of the Salmonidæ, and it opens the large ques-

tion how the migratory instinct became established in certain members of the family, when it appears not to be physiologically indispensable to them. At the period of migration, when the smolts are fit to go to the sea, they evince, I believe, the utmost restlessness (like all migratory animals), and frequently leap out of the fresh water in which they are confined, and die on the banks. This has taken place year after year in the nursery ponds on the Plenty River, Tasmania, where it was first placed beyond question that a migratory salmonid could remain and breed perfectly freely year after year in fresh water. On January 20, 1866, Mr. J. A. Youl, C.M.G., sent out to Tasmania a consignment of salmon, salmon-trout, and brown trout (*S. fario Ausonii*). On June 25, 1869, several parrs of the salmon-trout, then weighing in some instances more than a pound, were busy nesting, the result being that many thousands of fry from their ova were subsequently sent to stock other rivers. The imprisoned salmon-trout have continued to breed for several years in succession, but there has been noticed in them a tendency to become sterile as they grow older. There is also some reason to believe that *Salmo salar* has bred in the ponds on the Plenty. Two young specimens which, from certain circumstances, the Commissioners believed to be true salmon, were sent to Dr. Günther for examination, with full information as to their origin and history; and he, while expressing his reluctance to give a decided opinion, stated that they "presented all the anatomical characters of *S. salar*." Full details of the breeding in fresh water of *S. trutta* will be found in "The Acclimatisation of the Salmonidæ at the Antipodes—its History and Results." ARTHUR NICOLS

A Sea Monster

A FRIEND of mine, Capt. W. Hopkins, of the schooner *Mary Ogilvie*, who has just returned from a voyage all round Australia, has given me the following information, which I forward you for publication, not so much because of its interesting character, but in order that other travellers may throw some light upon the character of the animal, which, if an Octopus, must be of much larger dimensions than those usually met with. On June 15, when in S. lat. 21° 37′ and E. long. 113° 49′, about five miles off the Exmou'h Gulf on the western coast of the continent, he saw an immense creature which he took to be a species of Octopus. His attention was drawn to it by a perfect cloud of sea birds, and at first he naturally thought it must be a dead carcass. On approaching it, however, he found it was alive, and sluggishly disporting itself. In shape it was like a violin, but of immense size, with some six feelers about the greater diameters of the violin. It lay almost flat upon the water, was of a dark gray above and lighter gray below, and was continually elevating one of its feelers, apparently twice the thickness of a man's arm, to a height of from six to eight feet. It appeared to be vomiting, and as the birds were evidently feeding, that accounted for their presence in such numbers. Its size was so great that, had it grasped the vessel, it could easily have capsized it. The captain therefore got out of the way as quickly as possible, and without making definite measurements; but a large whale in the vicinity looked quite diminutive. It is a pity that something more exact as to size is not available, but I think the description is sufficient to convey an idea of the nature of the monster. All along the northern and western coasts of the continent vast shoals of pumice, in portions varying in size from ordinary gravel to about a foot in diameter, and completely covered with barnacles, were passed through.

Sydney, N.S.W., August 4 ALFRED MORRIS

Hail

WILL any of your readers kindly oblige me with particulars of the formation of a hailstone, and the effect produced upon it by falling through the air. How does it become frozen? increase in size? and what are the conditions for its increase? up to what point in its passage does it increase? what effect has temperature upon it in its downward career? after a certain point in its fall should it not theoretically decrease in size? does it do so actually? how is it that larger stones generally fall in tropical or hot climates during thunderstorms than we witness during our English winters? Does a raindrop increase in size as it nears the earth? If so, please give reasons. A. D.

Lisbon, September 1

[The best account of the formation of hail is given in Ferrel's "Meteorological Researches for the Use of the Coast Pilot," Part II. p. 85, a brief *résumé* of which is given in the "Encyclopædia Britannica," article *Meteorology*, p. 132.—ED.]

THE "COMMA-SHAPED BACILLUS," ALLEGED TO BE THE CAUSE OF CHOLERA[1]

WITH a view of studying the phase which the cholera question has now entered upon, in consequence of the publication of the results of the investigations of the German Cholera Commission in Egypt and India, I availed myself of the opportunity which the present vacation at the Army Medical School afforded of proceeding to Marseilles, where the disease has been prevalent since the end of June. Sir Joseph Fayrer was so kind as to enlist for me the valuable assistance of Dr. Le Roy de Méricourt, Médecin en Chef of the French Navy, who in various ways did his utmost to further my wishes. Dr. Marroin, the Chief of the Sanitary Department in Marseilles, was so good as to introduce me to the authorities of the Pharo Hospital, where the cholera cases are treated, and where, with the permission of the principal medical officer, Dr. Trastour, I was able to renew my acquaintance with the disease, and to collect material for studying afresh the microscopy of the intestinal discharges.

Before, however, referring to the results of my own observations, it will be convenient to epitomise the published history of the German Commission; to point out the salient features of the results of their investigations in Egypt and in India; and to make a few brief comments on such of the circumstances and conclusions as appear to call for notice. Shortly after the arrival of the Commission in Egypt, Dr. Robert Koch reported, on behalf of himself and his colleagues, that no special micro-parasites had been discovered in the blood, the lungs, the spleen, the kidneys, or in the liver in cholera, but that the intestinal mucous membrane was permeated by certain Bacilli which nearly resembled in size and form the Bacilli found in glanders. As is well known, these Bacilli are straight, and are, in fact, uncommonly like the ordinary microphytes associated with decay. Dr. Koch also states in connection with this subject that he had, previous to proceeding to Egypt, found similar Bacilli in the intestinal mucous membrane of four natives of India, but that he had then looked upon them as due to merely *post mortem* changes. When he came to Egypt, however, and found these same Bacilli in the intestines of perfectly fresh cases, he felt that an important link was furnished towards establishing the identity of the disease in Egypt with Indian cholera.

It is highly probable that the specimens from India which Dr. Koch had examined were those which were sent, at the request of the Imperial Health Department in Berlin, by the Sanitary Commissioner with the Government of India. These consisted of numerous dry cover-glass specimens of blood which I had collected from several cholera patients, and of portions of the viscera of four natives who had died of the disease. All these were examined by me before they were despatched, and portions of each were reserved for further study. I had heard nothing further of them, but the publication of the remarks above referred to in Dr. Koch's Report of September 17, 1883, from Alexandria, recalled them to my mind, and I was glad to infer that my own negative results had been confirmed in Berlin. As already observed, no importance had been originally attached to the organisms which were present in the intestinal mucosa. During the last six months I have examined hundreds of stained microtome-sections of these four, and of other specimens of cholera intestines in my possession, and have found that, when the mucosa is infiltrated with

[1] A Memorandum by Surgeon-Major Timothy Richards Lewis, M.B., Assistant Professor of Pathology, Army Medical School. Communicated by the Director-General, Army Medical Department.

microphytes at all, they are either Micrococci, Bacteria, or long-oval, and straight Bacilli.

In the Report of the Commission, dated Calcutta, February 2, 1884, Dr. Koch, however, announces for the first time that the specific Bacillus of cholera is curved or comma-shaped, and not straight; so that apparently it had become necessary to abandon the microbe first fixed upon. Assuming that the four specimens from natives of India which had been examined by Dr. Koch were those which passed through my hands, the evidence they furnish seems to be in accordance with this view, as in not one of them have I been able to detect any invasion by unmistakable "commas," though at least one of the specimens may fairly be characterised as abundantly infiltrated (in the manner described by Dr. Koch) by straight (and as I prefer to call them) putrefactive Bacilli. Judging from my own experience, therefore, any extensive infiltration of the intestinal mucous membrane in cholera by comma-shaped Bacilli must be exceedingly rare; and this, I believe, is likewise the experience of the members of the late French Cholera Commission, MM. Straus, Roux, and Nocard, whose acquaintance I had the pleasure of making at M. Pasteur's laboratory on my return through Paris.

Whilst at Marseilles I had, as already stated, opportunities of observing numerous specimens of choleraic excreta, and found that comma-shaped Bacilli were, more or less conspicuously, present in all of them, though in some instances more than one slide had to be examined before any could be satisfactorily detected. It may also be mentioned that some of the discharges in which these organisms were present manifested an acid reaction when tested with litmus paper. As Dr. Koch himself remarks, the proportion which the comma-shaped Bacilli bear to other organisms in the dejecta varies greatly. In some instances only one or two specimens are to be found in the field of the microscope, while in others they are very numerous, and Drs. Nicati and Rietsch (who are at present engaged in the study of the disease at Marseilles) were so kind as to show me a specimen of choleraic material they had obtained from the small intestine, in which the "commas" existed almost to the exclusion of all other organisms. This is a condition, however, which, I understand, is exceedingly rare. On the other hand, I have seen samples of choleraic dejecta in which totally different organisms prevailed to a like exclusion of others; and in one instance at Marseilles spirilla of various sizes and forms were the most conspicuous of the micro-organisms present. So far, therefore, the selection of the comma-shaped Bacilli as the *materies morbi* of cholera appears to be entirely arbitrary.

Dr. Koch and his colleagues have adduced no evidence to show that they are more pernicious than any other microbe; indeed, as a matter of fact, the sole argument of any weight which has been brought forward in favour of the comma-shaped Bacillus being the cause of cholera, is the circumstance that it is more or less prevalent in every case of the disease, and that the German Commission had not succeeded in finding it in any other. With regard to the suggestion that the cholera process may in some way favour the growth of these Bacilli, and that these are not necessarily the cause of the disease, Dr. Koch remarks, in the Report from Calcutta above cited, that such a view is untenable, inasmuch as it would have to be assumed "that the alimentary canal of a person stricken with cholera must have already contained these particular Bacteria; and, seeing that they have invariably been found in a comparatively large number of cases of the disease both in Egypt and India—two wholly separate countries—it would be necessary to assume, further, that every individual must harbour them in his system. This, however, cannot be the case, because, as already stated, the comma-like Bacilli are never found except in cases of cholera."

Had Dr. Koch and his colleagues submitted the secretions of the mouth and fauces—the very commencement of the alimentary canal—to a careful microscopic examination of the same kind as that to which they have submitted the alvine discharges, I feel persuaded that such a sentence as the foregoing would not have been written, seeing that comma-like Bacilli, identical in size, form, and in their reaction with aniline dyes, with those found in choleraic dejecta, are ordinarily present in the mouth of perfectly healthy persons.[1]

There is no difficulty in putting this statement to the test; and to any one acquainted with the methods ordinarily adopted for staining and mounting fungal organisms of this character, no special directions need be given. The procedure followed by me to demonstrate these "commas" in the saliva is precisely that adopted for finding them in the dejections. A little saliva should be placed on a cover-glass (preferably in the morning before the teeth are brushed) and allowed to dry thoroughly, either spontaneously or aided by a gentle heat. The dry films thus obtained should be floated for a minute or two with one or other of the ordinary solutions of aniline dyes adopted for such purposes, such, for example, as fuchsine, gentian-violet, or methylene blue. The cover should then be gently rinsed with distilled water, and the film re-dried thoroughly. The preparation may now be mounted in dammar varnish or Canada balsam dissolved in benzol, and should be examined under a 1/12th or 1/16th of an inch oil-immersion lens.

As in choleraic discharges so in the saliva the number of comma-shaped Bacilli will be found to vary greatly in different persons, and at different times in the same person. Sometimes only one or two "commas" will be seen in the field, at others a dozen may be counted, and, occasionally, little colony-groups of them may be found scattered here and there throughout the slide.

It may be remarked in passing, and as bearing upon what has been already said regarding the general absence of comma-shaped Bacteria from the intestinal mucosa itself, that they do not appear to manifest any special tendency for attacking the decaying epithelial scales of the mouth, but that, on the contrary, they are for the most

[1] Since this Memorandum was submitted, I have observed that Dr. Koch states, in his recent address on the subject, that, after his return to Berlin he had examined, amongst other things, the secretions of the mouth for comma-shaped Bacilli, but had found none; and, further, that he had consulted persons of much experience in bacterial researches as to whether they had ever seen such organisms, and was told that they had not.

It may be of assistance to future observers if I give the dimensions of half-a-dozen comma-shaped Bacilli as found in each of the following:—(*a*) In the alvine discharges of three cholera-affected persons; (*b*) in the small intestine of a person who had died of the disease and in whom they existed almost to the exclusion of other organisms; (*c*) in a cultivation of them in Agar-Agar jelly; and (*d*) in the secretions of the mouth of three healthy persons, ranging from four to fifty years of age. The measurements were made (with the valuable assistance of Mr. Arthur E. Brown, B.Sc. Lond.) under a magnifying power of 1000 diameters—a Powell and Lealand's 1/10th of an inch oil-immersion lens, with a wide angle condenser, being used.

part found free in the fluid, the epithelium being studded with other bacterial forms.

Persons who have not been in the habit of examining dried saliva-films will probably be surprised at the number and variety of the organisms which are, more or less, constantly to be found in the mouth; and especially at the number of spirilla with which the fluid is generally crowded.

The alvine discharges in cholera sometimes swarm with precisely similar spiral organisms, and, indeed, as has long been known, the fluid exuded into the intestines in this disease is peculiarly suitable for the growth of these and allied microbes. But, so far as my own experience—dating from 1869—of the microscopic examination of such a fluid goes, all the microphytes ordinarily found in it are likewise to be found, to a greater or less extent, in the secretions of the mouth and fauces of unaffected persons. And with reference to the comma-like Bacilli found in cholera, to which such virulent properties have been ascribed, I shall continue to regard them as identical in their nature with those ordinarily present in the saliva until it has been clearly demonstrated that they are physiologically different.

Pathological Laboratory, Netley, September 1

FORESTS IN COBURG, GERMANY, AND RUSSIA

A BLUE-BOOK under the title of "Reports by Her Majesty's Representatives abroad on the Cultivation of Woods and Forests in the Countries in which they reside," has just been published by Messrs. Harrison & Sons. These Reports are of an extremely interesting character, and we gladly draw attention to them, appearing as they do at an opportune moment before the close of the Forestry Exhibition at Edinburgh.

The Reports come from Coburg and Gotha, Germany, Norway, Russia, and Sweden, and in the form of an appendix is a *précis* by Dr. Lyons, M.P., of the Reports on Forestry of the United States Department of Agriculture. In each one of these Reports much valuable information is given and information of a very varied character. Thus in the first we are told that the forests in Gotha consist of 85 per cent. of pine and 15 per cent. of other wood. The principal timber-trees are pine and beech, whereas the remaining sorts of wood, namely Scotch fir, spruce, larch, oak, maple, ash, birch, and elm are found only in small quantities or mixed with the other species. The period during which the different woods are gradually brought into use is such that pine forests and mixed forests shall yield as large an amount as possible of saleable timber, whilst in the beech woods the greatest amount of wood as fuel is sought without allowing the trees to attain an age at which they would no longer pay the interest on the value of the soil. Pine and beech wood in higher situations are, according to these principles, usually cultivated and worked in cycles of one hundred years, while spruce on the lower heights and in the plains are worked on an eighty years' cycle. The woods for protection on the high grounds are subject to especial treatment, as no clear fellings take place, and care is taken to leave standing groups of foliage trees equally distributed over the whole surface. The usual rules followed are: early felling of the trees in a cycle of eighty years, leaving occasional large shelter trees, and utilising the undergrowth for purposes of renewal. The administration of the Domain forests in the Duchy of Coburg is carried on on scientific principles, and consists of regular felling at stated periods over certain areas; pine timber trees are usually cut every ninety years, while oak, ash, beech, birch, &c., are not cut till after 120 years' growth.

The Report on the general administration of Prussian State Forests treats of their organisation, expenditure, and results, and points to the desirability of introducing others than indigenous trees into the forests. On the subject of education in forestry it is stated that the School of Forestry at Eberswalde completed in June 1880 the fiftieth year of its existence, and had at that period in all nearly 1600 pupils. There is also a School of Forestry at Münden, and the half-yearly attendance at both schools showed in 1878 an average of 148 pupils, whereas in 1880 the number had increased to 210. The attendance was therefore largely on the increase, and it was then proposed to give voluntary education in these matters to the "Jäger Bataillonen" of the army. This plan has, according to latest accounts, been attended with so much success that the education has become obligatory, and forms a regular portion of their service.

From Russia a very elaborate Report treats, amongst other things, of the various kinds of trees found in Russia, with notes on their distribution, and some interesting facts on the consumption of wood and the uses to which it is put, showing that house and ship building consume a very large proportion, and that the minor industries when put together form a not unimportant total. After showing the extensive destruction of forests that has been going on in different parts of Russia for some years past, the Report considers the question of plantations along railways, the object of which is to protect the track from snowdrifts, and a list of the best trees and shrubs for this purpose is given. On the subject of tree-planting on the steppes of South Russia, it is stated that Count Kisseleff, when travelling through several provinces in 1840, found, much to his surprise, amongst the German colonists not only good kitchen gardens but also flourishing plantations of forest trees. The colonists had been obliged on every plot of land to plant a certain number of trees. The first experiences, however, were so severe that many of the colonists preferred to return to Germany; those that remained were forced to plant their allotments with trees which, with infinite trouble, they succeeded in doing, and these plantations are now a great ornament to the steppes, and from a climatic as well as an agricultural point of view have been of great importance to the colonists, and have laid the foundation of the planting which is now carried out on the steppes in a scientific manner. A forestry school was established, but closed in 1866, and the allowances for planting which had been granted were reduced to a minimum. Since that, however, matters have been put on a more satisfactory footing, and planting is conducted in a systematic manner.

STONE HATCHETS IN CHINA

LITTLE has yet been done to illustrate the Stone Age in China, and this is very likely to be true for some time to come from the fact that the people of the country worked in metals four thousand years ago.

To begin with the Han dynasty, B.C. 206 to A.D. 220, one chief source of revenue was iron in those days, and Shansi had grown rich and powerful because of her iron foundries. The correct Confucianists objected to the spirit of gain-seeking which they saw showing itself in the expansion of trade. In the reign of Chauti, B.C. 80, a book was written on the salt and iron duties, which was a record of the views then maintained by the purists of the Confucian school in contrast with those of the political economists of that day. The advantages of the encouragement of trade were detailed in full, and the sympathy of the modern reader goes with the economists, who saw that the strength and prosperity of the country must be increased by developing her resources. The country was then old, and the stone hatchet period must be sought much earlier. The same state of things existed in the time of Kwan chung, B.C. 700. Living before Confucius,

he could, as Minister of the Tsi kingdom, encourage trade without opposition from the literary class. His book speaks of the trade then existing between the different parts of China and the outside countries, and mentions gold as a product of the Ju and Han Rivers. Pearls come from the south; jade comes from Tartary; white ring plates come from the Kwun lun Mountain. Money was threefold. Pearls and jade were money of the first class. Gold was money of the second class. Knife money and cloth were money of the third class. This being the state of things at the beginning of the seventh century before Christ, the stone hatchet period must be sought farther back. It is said of the Emperor Cheng Tang, B.C. 1766, that he coined gold; and of the Emperor Shun, B.C. 2255, that he hid gold in the earth to check the covetous spirit of the people. In the book of history is recorded the tribute which was offered to the Emperor from various parts of China in the time of Yü, B.C. 2205. All the common metals were included among the articles offered.

Recently a stone hatchet was found near Kalgan in a mound forty feet high. The mound belongs to a large collection of graves, large and small, about seven miles east of the city Yü cheu, and 110 miles west of Pekin. An ancient wall, nearly round, twenty feet high and about eight miles in circuit, is still in existence there. The mound in which the hatchet was found is in the line of this wall—that is, the wall runs north-west and south-east from it. Hence the wall-builders did not regard the mound as sacred, for it would not in that case have been made to serve the purpose of a wall to their city on the south-west side.

There is another large mound known as the grave of Taì wang. It is a little to the east of the centre of the inclosed space once a city, and the principal road runs through the city by this mound from east to west. Rev. Mark Williams of Kalgan, who found the hatchet, and was the first foreigner to draw attention to the old city, was struck with the general resemblance of the mounds, the wall, and the hatchet to what he is familiar with in Ohio. So close was the similarity that it seemed to him to require that the same class of persons who made the one should have made the other.

A Chinese archæological work of the seventeenth century, "Fang yü kì yau," mentions the city but not the mounds. The city, it says, was built in the reign of Han kau tsu, B.C. 206 to 194. Han kau tsu gave to his brother Hì the title and principality of Taì wang, and this was his residential city. The traces remain (it is added in this book) of nine gates. A river from the north enters the wall in the west, proceeds to the south-east, and from thence flows to the Tsz River. This prince was attacked by the Hiung Nu Tartars, and they must have taken the city, for he fled to his brother in Shensi, and was degraded to a lower title of nobility for cowardice shown on this occasion. Before this, in the interval between the fall of the Tsin dynasty and the establishment of the Han, there had been two other persons who had been styled Taì wang. Hiang yü, who took the capital of the Tsin dynasty and burnt its palaces, resolved to restore the feudal system and made several kings.

Chau hìe was one of these, but he removed shortly after to a different locality. After this there was another occupant of this principality, Chen yü. He was appointed by the ruler of Chau. But soon Lieu pang subdued all China, and everything was changed. Besides these persons there is mentioned in the year B.C. 457 another Taì wang. The account which speaks of him is in the "Shih kì," chapter xliii., where the author is relating the fortunes of the house of Chau. The elder sister of the Prince of Chau was the wife of Taì wang. While brother and sister were in mourning for their father, the former invited Taì wang, his brother-in-law, to a feast, and directed the cooks to attack and kill him with their copper ladles, which they had first used in presenting food to him. The widow afterwards committed suicide with her hair-pin. The object of the ruler of Chau in the murder was to obtain the dominions of the Taì wang for himself. The people of the locality, adds the historian, pitied the unhappy queen, and after her death named the mountain where this event took place "the hill of the suicide with a hair-pin," *mo kì chï shan*. When the Prince of Chau had effected the murder, another work adds, he sent a messenger to his sister to say, "To feel indifference for a husband's death because it was caused by a brother would not be kindness. To hate a brother for a husband's death would not be right." After hearing this speech she committed suicide, and the envoy at once followed her example and put an end to himself. The feelings of the people were much stirred by these events, and it seems likely that one of the large mounds would be raised to the assassinated Taì wang. This however is not certain, and the number, names, and dates of other persons who bore the title are now beyond the reach of investigation.

Several pieces of broken pottery were found by Mr. Williams in the neighbourhood of the mound, and their pattern is different from modern crockery ware. The small mounds are in groups chiefly outside the wall, and seem to be all placed irregularly. The hatchet is about five inches long, and is made of a black stone not heavy when held in the hand. It resembles in shape those preserved in Ohio museums.

On the whole, as the reader of this account will agree, the highest of the two large mounds is most likely the tomb of the prince assassinated, in the manner here described, in the year B.C. 457. The village in the centre. and the large mound second in size near it, popularly called Taì wang, probably indicate that a later personage was buried there.

I should add to this statement that there is in Kwan chung a passage in the twenty-fourth chapter which is as follows:—"Hwan kung, ruler of Tsi, asked Kwan chung, 'What produce is there in the Taì country?' The philosopher replied, 'White fox-skins. They are, however, dear to buy. They appear in the sixth month, when the yang principle changes to yìn. If you, the ruler of Tsi, offer to buy them at a high price, the people of the Taì kingdom will at once, from the hope of gain, go out in force to hunt for them. Tsi keeps its gold and waits. While the Taì people are hunting in the wilds and off their guard, their enemies on the north, the Lai ti, will attack them, and in this case the Taì country will fall to Tsi.' The ruler of Tsi adopted this plan for obtaining possession of Taì, and sent envoys with money to negotiate for white fox-skins. The King of Taì, hearing what they desired, said to his chief councillor, 'The money offered to us by Tsi is the very thing for want of which we are not equal to the Lai ti people. It is fortunate that this proposal is made to us.' He then ordered his people to go out hunting for white fox-skins. During twenty-four months they searched without finding any. The Lai ti people learned that the Taì kingdom was not in a state of defence, and attacked its northern frontier. The Taì wang in great fear gathered his troops and posted them above a defile called the valley of Taì. The invasion proceeded, and the Taì wang took his soldiers with him and submitted to Tsi. So in less than three years Taì submitted to Tsi without its being necessary to spend any money on the purchase of the skins which Kwan chung praised."

This passage must by fair criticism be ascribed not to Kwan chung himself but to some unknown author of the age of the contending States three or four centuries later. There was no Taì kingdom in the time of Kwan chung, and invention of this sort was common in the period of the contending States. Kwan chung had ascribed to him many expedients of statecraft which never occurred to him, and this of the fox-skins was amongst them.

JOSEPH EDKINS

NOTES

M. JANSSEN has been appointed by the Paris Academy of Sciences to represent the French Government in the Congress which is to be held at Washington to determine the choice of the first geographical meridian. It is just to state that the original idea of a universal first meridian belongs to France, and that as far back as 1632 a decree signed by Louis XIII. and proposed by Cardinal Richelieu established a universal meridian on the island of Ferro. This meridian was ultimately abandoned by Cassini to gratify Louis XIV.'s pride, and the Paris one was retained by the Metric Commission in 1793 under the pretence that an arc of this meridian had been measured for determining the length of the unit of measure.

WE regret to announce the death of Dr. Heinrich Schellen, formerly director of the Cologne Realschule, and author of two well-known works, "Der electromagnetische Telegraph" and "Die Spektralanalyse." Besides these, Dr. Schellen published a book on arithmetic, an excellent German version of Padre Secchi's great work on the sun, and various other works on physical subjects. It was under his directorship and by his efforts that the Cologne School was raised from the rank of "Bürgerschule" to that of "Realschule erster Ordnung," and that it attained the high reputation it now enjoys. He died in Cologne in the first week of September, aged sixty-six years.

WE regret to announce the death of M. Jean Augustin Barral, the Perpetual Secretary of the French Société d'Agriculture, and the chief editor of *L'Agriculture*, a periodical of large circulation, and which, of all the Continental agricultural papers, was the most intensely devoted to the adaptation of English principles of rural economy to French conditions. M. Barral was born in Metz in 1820, and was a pupil of the Polytechnic School, where he was a *répétiteur* of chemistry for some time. He became most intimately connected with Bixio, the editor of *Maison Rustique*. Bixio and Barral made two daring aëronautical ascents from the Observatory grounds in 1850, when they ascended to an altitude of 18,000 feet, a height unsurpassed except by Glaisher and Tissandier. When Arago died he selected M. Barral, who had acted as his secretary for a long period, to publish his works. The Barral edition contains twelve large octavo volumes, exclusive of the "Astronomie Populaire," which fills four other volumes, and has been translated into almost every language. M. Barral edited the *Revue Horticole* and the *Journal d'Agriculture Pratique* for many years; it was on the occasion of the death of his friend Bixio that he resigned and started *L'Agriculture*, of which he was not only the editor but also the proprietor. He edited for ten years the *Revue de la Presse Scientifique*, an influential paper whose publication was stopped after a brilliant existence of eight years. M. Barral was a very popular character, much appreciated in Paris, where his loss will be heavily felt. Besides his editorial work he has written some popular works on scientific topics, and he leaves a number of academical essays, of which some have been edited under the form of pamphlets.

THE death is announced at Meran of Dr. Settari, one of the authorities on Lepidoptera.

A WARSAW correspondent informs us that on the 16th inst. there died in that city Jakób Natanson, formerly Professor of Chemistry in the principal school there. The late Prof. Natanson prepared carbamide synthetically by the action of ammonia gas on phosgene ($COCl_2$) in 1856. Prof. Natanson wrote many scientific papers in the Polish language; the most valuable are a text-book of chemistry ("Krótki mykład chemii organicznéj") and a treatise on organic chemistry. He also improved the methods of determining the density of vapours.

MESSRS. CASSELL AND CO. announce the forthcoming publication of "A History of British Fossil Reptiles," with 268 plates, by Sir Richard Owen, K.C.B. The edition, it is stated, consists of 170 copies only (each copy being signed by Prof. Owen), and no further number can be produced, as the plates from which the illustrations have been printed have been destroyed.

THE German Association of Naturalists and Physicians met last week at Magdeburg.

THE French Association for the Advancement of Science has decided that its next meeting will be held at Nancy. The President of this session, which promises to be most interesting, will be M. Friedel, member of the Academy of Sciences and Professor of Chemistry at the Sorbonne. The general secretary will be M. Collignon, Professor of Mechanics to the École des Ponts and author of the text-book on mechanics used in almost every French academy.

THE autumnal meeting of the Iron and Steel Institute was opened at Chester on Tuesday, when Dr. Percy, F.R.S., was elected President.

THE Social Science Congress has been meeting at Birmingham during the past week. In the Education Department Mr. Oscar Browning was President, and in his inaugural address he contrasted the ardent desire for a University education displayed by the Germans, who were content to beg to obtain it, with the apathy displayed in England. Our primary education was organised in a manner which became more effective every year. A complete system of University education which should lead the best scholars from the primary school to the University, and which should educate the bulk of the middle class, could not be said to exist. This was a crying want; it paralysed the activity of England in many directions, and the want could not be adequately supplied without the initiative of the State. On the Continent there might be too much theory and too little practice, but in England we had suffered until lately from having no theoretical training at all. He advocated such a technical education as that by which the Continent had progressed so much during the last half-century. Contrasting Germany and England he showed how a youth naturally fitted for an academic career could, however poor, by State aid go to the German University, while he had no such sure road in England. The best means by which this deficiency in our national life could be supplied, he thought, would be, first, by putting ourselves on an equality with other nations by determining that in every town in England of a certain size there should be at least one State school, where, for a very moderate charge, an education of the classical type should be given equal to the best which the country could supply, and that by the side of this, either in the same school or in a separate establishment, according to the population of the town, there should be facilities for passing a curriculum of modern education which should fit a man either for a commercial or for a scientific career. It could not be hoped that such schools would be self-supporting, and the time would come when the amount contributed by the Budget to national education would mark the national prosperity.—In a paper in the same Section, Dr. H. W. Crosskey said that in order that science may be effectively taught in public elementary schools, it must be taught experimentally. Actual demonstrations must accompany the lessons at every stage. It must be taught systematically and continuously. The "getting up" of some branch of science during three or four months as a "specific subject" is of little use. Special science demonstrators must be appointed. No man can be a good demonstrator who does not devote to the work the greater part of his daily

life. The ordinary master of a school has many duties to discharge. He cannot by any possibility give any sufficient proportion of his time to the art and practice of scientific demonstration. By the peripatetic system experimental lessons can be given at every school, by a trained man of science, at a moderate cost. A central laboratory is erected in which experiments are prepared. The demonstrator visits each school in succession, the apparatus being brought by a hand-cart from the laboratory. The results actually attained in Birmingham were described. It was argued that experimental teaching gives the death-blow to cram, and that the elements of ordinary education are better mastered when the intellectual life of the scholars is aroused by science. The arrangements of the peripatetic system will suffice until the Sixth Standard is passed; but special provision must be made for those lads who can remain a year or two longer at school, and whose future employments render the extension of their scientific training desirable. To meet the wants of this class, a school has been opened as an experiment in New Bridge Street, Birmingham, in premises belonging to the Chairman of the Board (Mr. George Dixon), who, at the cost of more than 2000*l.*, has adapted them for the purpose, and placed them rent free at the service of the Board. It is specially intended for scholars who will have to become working-men, but whose parents can keep them at school after they have passed the Sixth Standard, and the fee (3*d.* a week) is adapted to their means. There is a special master for chemistry and metallurgy, another master for mechanics and physics, a drawing-master, and a mathematical master, a highly-qualified scientific man being placed at the head. Workshop instruction is provided, and includes a knowledge of the chief wood tools, and the properties of materials, while it supplements the mechanical drawing of the schoolroom, and it is an aid to the study of theoretical mechanics. The course of instruction is arranged to extend over two years. It is not an attempt to benefit a few picked scholars, or to provide a higher-grade school for those able to pay high feees, but it is a continuation of the science training given by means of the peripatetic method in every ordinary elementary school under the Board.

THE Americans are not content with an Electrical Exhibition at Philadelphia; we see that there is to be another at Boston this year, opening on November 24 and closing on January 5, 1885. Space and power to be found free, but there is an entrance fee of ten dollars. The object of the Exhibition is stated to be "to show the rapid advancement that has been made in electricity, its methods and appliances, and all its possibilities and probabilities."

WE are requested to announce that the Fifth Annual Cryptogamic Meeting of the Essex Field Club will be held on Friday and Saturday, October 3 and 4, in Epping Forest. The meeting will be under the direction of Dr. Cooke, Dr. H. J. Wharton, Mr. Worthington Smith, Rev. Canon Du Port, Rev. J. M. Crombie, Prof. Boulger, Mr. David Houston, Mr. F. J. Hanbury, Mr. Henry Groves, Mr. W. W. Reeves, Dr. Spurrell, and other well-known botanists. Those wishing to attend the meeting should apply for programmes and tickets to the Honorary Secretary, Buckhurst Hill, Essex.

WE stated some months ago that Capt. Scheele of the Swedish trading barque *Monarch*, before leaving Sweden for Melbourne, had asked the Zoological Museum at Upsala to lend him the necessary apparatus, vessels, &c., for deep-sea researches, with which request the Museum gladly complied. The results appear to have been so fruitful, that the *New York Herald* and the *Sun*, on the vessel recently arriving in New York, sent representatives on board, and devoted a great deal of space to descriptions of the collection made by "the intelligent Swedish seaman." The collection is, it is stated, very rich, filling two hundred vessels, and contains many new varieties. It will be forwarded to Upsala, while Capt. Scheele proceeds with his scientific researches during a voyage to the West Indies.

ONE of the most remarkable articles of export ever despatched for scientific purposes from any country is without doubt the consignment which has just left Norway for Germany. It is no less than fifty-two skeletons of Lapps, which have during the summer been unearthed at Utsjok in Russian Lapland, and which an enterprising dealer of Vardö has sold to various museums and societies on the Continent at the price of 6*l.* a piece. Two of the skeletons are those of children, the rest those of adults.

THE Berlin Academy of Sciences has commissioned Dr. Georg Volkens, a young botanist, to proceed to the sulphur-baths of Heluan, which are situated some 20 kilometres west of Cairo, in order to make a thorough investigation of the anatomy of desert plants, and microscopical researches concerning the growth of these plants.

UP to the present the North Cape on Mager Oe was considered to be the northernmost point of Europe. Capt. Sörensen, however, has recently found that Cape Knivskjaerodden, on the same island and west of the North Cape, lies 30″ to the north of the latter; 30″ of arc would correspond to about 926 metres. The latitudes found by Capt. Sorensen for the two capes are 71° 10′ 15″ N. for the North Cape, and 71° 10′ 45″ N. for Cape Knivskjaerodden.

A SEVERE earthquake occurred at Windsor, Ontario, at a quarter to three on the afternoon of September 19. Shocks were felt at twenty minutes past two at Grasslake, Michigan, where some school children fainted with alarm, and at Toledo, Ohio, and neighbouring towns. The shocks lasted fifteen seconds, and in some instances buildings rocked and their contents were displaced.

MM. D. TOMMASI AND RADIQUET have brought out a new battery with two carbon electrodes. The positive electrode consists of a carbon plate placed at the bottom of a porcelain vessel and covered with peroxide of lead, the negative electrode consists of a carbon plate containing on its upper surface platinised coke. The two plates are separated by a sheet of parchment paper. The liquid used is a saturated solution of common salt, which must not completely cover the upper plate. The E.M.F. on closed circuit is 0·6 volts.

IN a paper on "Electric Lighthouses" M. De Meritens gives some very interesting figures in comparing oil and electricity as illuminants. The figures, he states, are taken from two memoirs by M. Allard. As an example, the light at Dunkirk, obtained from mineral oil, is 6,250 candles, which in weather of mean transparency is seen for 53 km.; if this be compared with an electric light of 125,000 candles, it is found that the electric light is seen for 75·4 km. Thus, an increase in the illuminating power of twenty times only increases the penetrative distance 22 km. or 42 per cent. If we now take a less transparent state, the ratio is reduced to an increase from 24 to 32 km. or 34 per cent. Or, lastly, in very foggy weather the distances are 3·7 and 4·6 km., showing an increase of 24 per cent. From these general figures M. Allard has calculated that in foggy weather in the Channel the luminous intensity with oil of 6250 carcels is 3·805 km.; then, if this be increased to an oil illumination of 125,000 carcels, the luminous intensity of 4·740 km. Now, comparing this with an electric light of 125,000 carcels, he finds the luminous distance to be 4·696, or the penetrating power of the electric light is less than 1 per cent. less than mineral oil, whilst its cost, as computed by both English and French engineers, is from four to six times less than that of oil.

THERE is unfortunately now no doubt that Phylloxera has begun to appear in Rhenish Prussia. The districts of Heimersheim and Lohrsdorf in the valley of the Ahr are hopelessly infected and considered lost. Every effort is being made to prevent the pest from spreading.

THE Japanese appear to be determined to render themselves, as far as possible, independent of foreign countries. They have, says the *Pharmaceutical Journal*, established in Tokio a factory for the production of pharmaceutical chemicals on a large scale. A company with a capital of about 40,000*l.* has been formed for this purpose. Of this amount the Government has contributed one-half free of interest for twenty years, besides making a free grant of land and erecting the necessary buildings. A similar company is taking up the utilisation of the waste *saké* from the native breweries in the manufacture of alcohol, and the manufacture of bleaching-powder on a large scale has been commenced. Whether with the object of "protecting" the first of these enterprises or not does not appear, but we learn from the same authority that an increased tax has been placed in Japan on imported patent medicines, and the nature of the articles to which this has been extended is stated to have largely affected the import of some chemicals into that country. Santonin, which was at one time much in request among the Japanese, decreased 20,000 ounces in import last year, although the price was lower; on the other hand, the consumption of quinine showed an increase.

IN a paper read before the Vaudois Society of Natural Sciences, M. Schnetzler explained the results of his studies on the colour of flowers. He argues that only one colouring substance exists in plants, and that the various colours of flowers are only due to the modifications made in this substance by the acids or alkalis contained in the plants themselves.

A VICTORY has been gained by Van Rysselberghe in Belgium by the solution of the problem of transmitting a telegraphic and a telephonic message along the same wire at the same time. A trial of this has been made at the Antwerp Universal Exhibition, where concerts held in important towns in Belgium were heard; the transmission being made with ordinary instruments along ordinary telegraph lines and with earth returns.

M. COLLADON has observed a curious phenomenon connected with hailstones. He observed, on some occasions, that two or three seconds after they had fallen they sprung into the air again, to a height of 0·25 m. or 0·30 m., as if they had been struck upwards by the earth.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus* ♂), a Ludio Monkey (*Cercopithecus ludio*) from West Africa, presented by Mr. A. Bowden; an Australian Fruit Bat (*Pteropus poliocephalus*) from Australia, presented by Capt. C. D. Long; a Tawny Owl (*Syrnium aluco*), British, presented by Miss H. Freeman; a Coypu Rat (*Myopotamus coypus*) from South America, presented by Mr. Frank Parish, F.Z.S.; two Black-billed Tree Ducks (*Dendrocygna arborea*) from Antigua, West Indies, presented by Mr. C. Arthur Shand; a Blackcap (*Sylvia atricapilla*), British, presented by Mr. H. Keilich; a Spanish Terrapin (*Clemmys leprosa*), South European, presented by Master A. Brierly; a Horned Lizard (*Phrynosoma cornutum*) from California, presented by Mr. Alfred R. Wallace, F.Z.S.; an Indian Python (*Python molurus*) from Ceylon, presented by Mr. A. A. Dalmege, F.R.G.S.; a Bonnet Monkey (*Macacus sinicus*) from India, two North African Jackals (*Canis anthus*) from Spain, deposited; two Half-collared Turtle Doves (*Turtur semitorquatus*), two Triangular-spotted Pigeons (*Columba guinea*), two Bronze-spotted Doves (*Chalcopelia chalcospilos*), four Harlequin Quails (*Coturnix histrionica*), an Allen's Porphyrio (*Hydrornia alleni*) from West Africa, received on approval; a Levaillant's Cynictis (*Cynictis penicillata*), three Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE FIGURE OF URANUS.—In a note communicated to the Reale Accademia dei Lincei, Prof. Millosevich collects the measures of Uranus which have been made by various observers, and adds the results of several series made by himself at the Observatory of the Collegio Romano. While the recent measures of Schiaparelli at Milan are in accordance with those of Madler at Dorpat, as regards a very sensible ellipticity, most observers have failed to recognise, or at least have not referred to, any measurable quantity, amongst them Engelmann, Vogel, Lassell, Marth, and Kaiser. It is a point which might be expected to be readily settled if large telescopes were brought to bear upon it, and particularly if the double-image principle of measurement were employed.

THE LUNAR ECLIPSE ON OCTOBER 4.—During this eclipse the moon will be in a somewhat bare part of the sky, and with one exception no star brighter than the tenth magnitude will be occulted while she is immersed in the earth's dark shadow, or between 9h. 16m. and 10h. 48m. One of the tenth magnitude, of which an accurate position is given in vol. vi. of the Bonn Observations disappears at 9h. 33m. 35s. and reappears at 10h. 37m. 54s., the angles being respectively 137° and 271°; No. 800 of Weisse's Bessel, 0h. R.A., disappears at 10h. 35m. 24s. at 100°, but does not reappear till 11h. 45m. 35s. (308°) when the moon will have begun to emerge from the shadow; this star is estimated 9 m. by Bessel. The times are for Greenwich.

OLBERS' COMET OF 1815.—In Nos. 2613 14 of the *Astronomische Nachrichten* Prof. Krueger has printed the sweeping-ephemerides for this comet calculated by Herr Ginzel of Vienna, at least between the dates October 1 and January 1. Although the epoch of perihelion passage directly resulting from the computation of the perturbations during the present revolution does not fall before December 1886, the discussion of the observations in 1815 left an uncertainty of ± 1·6 year in the time of revolution at the instant of perihelion passage in that year, and it may be well to commence a search for the comet forthwith; it is to be remarked, however, that, should it reach perihelion in midwinter in these latitudes, it is not likely to pass unobserved, the intensity of light b
a high north declinatio

THE COMET OF 1729.—"La Comète de 1729 est de toutes les comètes, observées jusqu'en 1780, celle qui a été vue à la plus grande distance du Soleil et de la Terre," writes Pingré in his "Cométographie." Upwards of a century has since elapsed, and yet no comet observed in the meantime has had a perihelion distance at all approaching that of the comet discovered by Père Sarabat at Nismes on July 31, 1729. The comet was seen until the end of January following, and was observed by Cassini until the 18th of that month. From some of his observations newly reduced, Burckhardt calculated both parabolic and hyperbolic orbits which were first published in the *Connaissance des Temps* for 1821. Recently, employing Burckhardt's reductions of Cassini's observations on September 3, November 10, and January 16, Mr. Hind has found the following parabolic elements:—

Perihelion passage, 1729, June 16·15422 M.T. at Paris

	°	′	″	
Longitude of perihelion	321	2	46·1	Mean
ascending node ...	310	37	8·3	Equinox
Inclination	77	4	6·0	1730·0
Logarithm of perihelion distance..	0·607513			

Motion—direct

By which the middle observation is represented within 16″ in longitude and 10″ in latitude. The distances from the earth and sun at the times of the three observations are:—

1729 Sept. 3 ..	From Sun,	4·107 ...	From Earth,	3·142
Nov. 10 ...	„	4·240 ...	„	4·339
1730 Jan. 16 ...	„	4·439 ...	„	5·132

The distance in perihelion is 4·05, the earth's mean distance from the sun being taken as unity. The comet of 1747 had a perihelion distance of 2·198, which is the nearest approach to that of the comet of 1729; it was a very exceptional and extraordinary body.

CONSTITUTION AND ORIGIN OF THE GROUP B OF THE SOLAR SPECTRUM[1]

WHEN a single prism spectroscope is directed towards the sun at the moment when it is in the neighbourhood of the zenith, we perceive near C, at about a fourth of the distance separating it from the extreme red, a strong black line, which Frauenhofer has named B. Under a more powerful instrument of five or six prisms this line becomes a very black broad band, separated from the region of C by what may be described as almost an empty space, the lines which do exist in it being few and faint. On the other side this band is followed by well-marked lines, which appear to be very regularly spaced, and the first of which show some indications of being double. Father Secchi had vainly attempted to resolve the band B; on this subject he writes:—

"Certain bands which in ordinary instruments seem to be stumped consist in reality of numerous perfectly distinct lines, as is seen in a spectroscope possessing great dispersive power; but some of them are really massed towards the edge, and there it is impossible to separate them, however powerful the instrument employed. We may cite as an example the lines of the group B" (*Le Soleil*, vol. i. ed. 1875, p. 235).

The statement of the learned physicist shows that, at the time he wrote the above, spectroscopic apparatus had not been brought to very great perfection or power. In point of fact the dispersion of eight or ten prisms suffices to show that the band B is really formed of a large number of distinct lines. With my highly-dispersive instrument it becomes resolved in a truly marvellous manner. The seventeen lines composing it are distinguished with the greatest clearness, and may be very exactly measured. Those following it on the red side are all broadly doubled, presenting in their regularity a very remarkable appearance.

In 1878 Messrs. Piazzi-Smyth and Langley succeeded for the first time and almost simultaneously in resolving this group. Piazzi-Smyth, working with prisms, obtained only an incomplete resolution, whereas, by means of Rutherford's excellent appliances Langley not only separated all the lines, but also determined their wave-lengths. Being unaware of the work of these physicists, I fancied I had been the first to obtain these results in 1879, when making the first essays with my highly-dispersive apparatus. The sulphide of carbon compound prisms, which M. Laurent had just made, were merely mounted on a drawing-board, were badly regulated, badly sheltered from variations of temperature, and could not yield the results that I now obtain. The drawing which on that occasion I published in the *Comptes Rendus* is incomplete and inaccurate. That

Solar Spectrum—Region B, by M. L. Thollon.
Position of the lines.
Mean aspect of region B when the sun is 80° from the zenith.
" " " 60° " moist weather.
" " " 60° " dry "
Non-telluric lines. Spectrum of region B as it would appear if observed outside the atmosphere.

which accompanies this article has been made with the greatest care and to a scale on which the errors of position can scarcely exceed 1/10 mm. It is more complete than any I have yet seen.

The explanations given at the foot of my design enable us to recognise at a glance: (1) the metallic lines, (2) the telluric lines produced by the variable element of the atmosphere (beyond all doubt aqueous vapour); (3) the telluric lines proceeding from the constant elements (oxygen, nitrogen, carbonic acid). The group is thus seen to consist of a pencil of seventeen rays, constituting properly speaking Frauenhofer's B-band; of a system of twelve couples with intervals increasing regularly from right to left, whereas the distance of the constituents diminishes with equal regularity in the opposite direction; lastly, of a somewhat important group belonging to the vapour of water, the whole interspersed with a few weak metallic lines.

When we survey the solar spectrum given by my apparatus, beginning with the violet, and when we behold the thousands of lines composing it distributed in all the regions without any apparent kind of order, on arriving at the group B we feel, as Mr. Langley remarks, the same impression as does a traveller lost in a virgin forest when he suddenly finds himself in the presence of a perfectly straight avenue of trees planted with mathematical regularity. It should be added that A at the extreme red, and *a* comprised between C and D are identically constituted. If they attract less attention it is because A is nearly at the limit of the field of vision, while the regularity of *a* is disguised by a large number of lines foreign to its origin. Beyond these three cases chance alone seems to have presided over the distribution of lines throughout the whole spectrum.

But the interest attaching to these groups is due not only to their remarkable appearance, but also and especially to the question of their origin. In what regions are produced the absorptions which give them birth? In the solar atmosphere, in the terrestrial atmosphere, or in some medium comprised between the sun and the earth? Do these absorptions proceed from a common element, and if so what is its nature? The most contradictory answers have been given to these various questions, which have already long since been asked.

To speak only of B, after his memorable experience of La Villette in 1866, M. Janssen asserted that this group was at least to a great extent due to aqueous vapour. The little sketch lished by him in the *Annales de Chimie et de Physique* series, vol. xxiv. p. 217) in fact shows, facing B, bands absorption due to the vapour of water, and correspond exactly to the spectral bands yielded by the setting sun in region. On the other hand, Ångström, who had devoted much study to the question, tells us that at the low temperature of 27° C.,

[1] Paper by M. L. Thollon in *Bulletin Astronomique*, May 1884.

when the other telluric lines had almost entirely disappeared, he saw B perfectly distinct. At a like zenith distance from the sun this group seemed to him even blacker and more intense than usual. Hence his inference that it could not proceed from the vapour of water. This eminent physicist, a thoroughly convinced partisan of spectral unity for the simple gases, had ascertained that in the spectrum of atmospheric emission there was no trace of any ray or band corresponding to B. It followed for him that the air could not absorb radiations it was incapable of emitting. If therefore this group, variable like the other telluric rays, could be attributed neither to aqueous vapour, to nitrogen, nor to the oxygen of the air, from what element did it derive its origin? Angström spoke of carbonic acid, but perhaps without believing in it. He seemed deeply interested in Tyndall's experiments on the absorbing power of gases by heat. We know that this skilful investigator had found that the coefficients of absorption of oxygen and nitrogen by no means corresponded with the coefficient of absorption of the air. The difference he attributed to some unknown element sufficiently rarefied to escape our analyses, and endowed with immense absorbing power. Ångström had probably this unknown element in his mind, but he remained uncertain to the last.

The great authority of the Swedish physicist could not fail to have its influence on the judgment of those approaching the question after him. Captain Abney, who has so greatly distinguished himself by his remarkable scientific labours, asserts in NATURE (October 12, 1882, p. 585) that the groups A and B cannot be regarded as telluric, but as proceeding from a medium lying between the sun and the earth. Piazzi Smyth, who had at first looked on B as telluric, seems to have finally adopted Captain Abney's views, and is disposed to think that B as well as A may after all be the product of some interplanetary medium. In his opinion the recent theories of Siemens seem to confirm his view of the case.

The attention that I have for several years paid to the portion of the solar spectrum stretching from A to *b* has naturally led me to deal with this subject. Here is the method by which I succeeded in separating and classifying the spectral lines. After certain preliminary measures taken with the greatest care to determine their exact position, each region of the spectrum is drawn on two maps. The first is intended to reproduce the appearance of this region when the sun is at 60° from the zenith, the second when at 80°. These distances have been chosen in such a way that in the latitude of Nice the observations may be continued throughout the year. When the weather seems favourable at the hour when the sun is in the desired position, the intensity of each line is marked on the map itself with all possible exactness, the hygrometric state of the air being indicated each time. The process is slow, delicate, and laborious, but the result is certain. After I have thus made eight or ten series of observations on each drawing, they are carefully examined, and the indications relative to any given line enable me confidently to decide:—(1) whether it is not metallic; (2) whether a telluric line belongs to a constant or to a variable atmospheric element. By this method I have been able to satisfy myself that A, B, and α are telluric groups due to the constant elements of the air. *At the same distance from the zenith they have always the same intensity.* I refer of course only to the main groups in each of them, and to the couples following them on the least refrangible side.

It remained to determine exactly to what atmospheric element the groups in question were to be attributed. M. Egoroff, Professor of Physics at the University of Warsaw, has recently succeeded in solving the problem. He had for several years ardently devoted himself to this inquiry, and in 1882 we jointly made a series of experiments on the subject in the Paris Observatory. A pencil of electric light directed from Mount Valérien on the Observatory, distant 10 km., gave us the spectrum of the telluric rays all but complete. There was no difficulty in distinguishing A, B, and α, which are so easily recognised. Capt. Abney has questioned the results obtained by us. Yet they are incontestable, and in any case the experiment can be easily repeated.

At last, after these preliminary studies, M. Egoroff, operating directly on oxygen closely compressed in a metallic tube, and traversed lengthwise by a pencil of strong light, has obtained the groups A and B. The thickness of the oxygen thus traversed was doubtless insufficient for the production of α. But however this be, it may now be confidently asserted that these three, which are of such remarkable appearance, and which so closely resemble each other, have their origin in the absorption due specially to atmospheric oxygen.

I need not dwell upon the importance of this result; but how is it to be reconciled with the observations of Messrs. Janssen, Ångström and Piazzi Smyth? To judge from the sketch contained in the *Annales*, and above referred to, M. Janssen must have seen in the spectrum of aqueous vapour bands corresponding to those of the solar spectrum in the region of B. One of them even coincides exactly with the chief member of the group. According to my own observations, to produce this effect the vapour of water would have to yield at this point a non-resolvable band, which would simply obscure the intervals between the lines, as is seen in the spectrum 1 of my drawing. This observation should then vary according to the hygrometric state of the air, and not, as it has always seemed to me, according to the height of the sun. Or else this band is not represented in the exact position it ought to occupy, and should be shifted more to the left, where in fact are found many lines of the vapour of water constituting an important group (see plate).

If, on the other hand, Ångström saw B more intense at a temperature of 27° C., it was doubtless owing to a simple effect of contrast. The other telluric lines being greatly weakened, those that retain their intensity must naturally appear blacker. Such an effect is frequently produced in the course of my observations, and against it I have to be constantly on my guard. And now how can we explain why the spectrum of absorption of the oxygen differs so much from its spectrum of emission? The lack of sufficient data renders all explanation impossible; but the certainty of the fact obliges us to conclude that *cold* has not the same properties as *incandescent* oxygen, and allows us to suspect that it may be the same with all gases.

In asserting that A and even B do not really vary in intensity when the sun approaches the horizon, such an eminent observer as Piazzi Smyth would have greatly surprised professional spectroscopists, were they not aware how difficult and delicate a matter is the management of an apparatus of highly dispersive power. Let but the luminous pencil be badly adjusted, the prisms less than faultlessly regulated, the slightest cloudiness settle on the surfaces, the images, especially in the extreme red, will at once appear as if drowned in the diffused light, which obscures the most evident effects and even disfigures their essential characters. Strange phenomena are often produced, the causes of which it seems impossible to discover, and which easily give rise to illusions. But when we work under favourable conditions with a well-designed and well-constructed apparatus, it becomes superabundantly evident that A and B vary considerably in intensity according to the height of the sun, and are certainly telluric.

During the total eclipse of 1882, both M. Trépied and myself fancied we observed on the edge of the lunar disk a notable strengthening of the rays of the B group. If Captain Abney's theory could have been confirmed, it would have certainly added great weight to our observations, and for my own part I should have felt highly satisfied at the result. Unfortunately, the atmosphere of oxygen which should now be attributed to the moon in order to produce the observed effects, seems scarcely reconcilable with the absence of refraction in the luminous rays striking the edge of our satellite. I greatly fear the results obtained in Egypt are one of those illusions, of which nearly all spectroscopists have been more or less the victims.

It would now be important to ascertain whether the nitrogen and carbonic acid of the air may not be represented by any line or any group in the solar spectrum. The study I am at present engaged in, according to the above described method, will not fail, I trust, to yield precise results on this important point. Hitherto, apart from the oxygen groups, I have discovered no line that may be confidently attributed to the constant elements of the atmosphere. Hence it is desirable to await the result of my researches before giving effect to the project adopted by M. Bischoffsheim to establish on Mont Gross metallic tubes of considerable length, in which the spectra of absorption of gases may be studied on a grand scale.

THE MIGRATIONS OF "SALMO SALAR" (L.) IN THE BALTIC

THE following statement gives further details supplementary to our recent article on this subject:—

Since the earliest times salmon have been caught in the Finnish rivers which had in their mouths or entrails hooks

of a peculiar shape entirely unknown in Finland. Such hooks have been found in salmon taken in all Swedish and Finnish rivers falling into the Gulf of Bothnia. At one of the salmon fisheries in the Uleå River, for instance, where the fish is sold cleaned, twenty-five such hooks, all of brass, were collected last summer and handed to me. With a few exceptions the hooks are of one kind, viz. made of brass wire 2 to 2·5 mm. thick, a little compressed in the hook itself, while the length varies from 9·5 to 11·5 cm. Most of the hooks are 10·5 cm. in length, and the width of the bend 2·5 to 3·5 cm. Generally a bit of line 1 to 2 mm. thick, made of flax, hangs to the hook, while, when the line is long enough, a lead, conical in shape and 10 to 20 grm. in weight, is found on the same. Sometimes Latin characters are engraved on the lead, as, for instance, in one taken in the above-mentioned river last summer, which had on it "C" and "K" on each side. I am of opinion that all the hooks which have passed through my hands are of the same type and manufacture.

As it is of great practical value to discover whence these peculiar brass hooks have come, I have given considerable attention to the question, the result of which is that I have come to the conclusion that they were brought from the north coast of Germany, where they are used for salmon-fishing in the winter. Great fisheries are carried on along this coast in a depth of 30 to 60 m. and 10 to 30 km. from the shore, as far as, and probably beyond, the Russian frontier. The lines used are very like those used on the south coast of Sweden, but the hooks and leads are quite different. Prof. Benecke, of Konigsberg, to whom I sent a hook taken from a salmon in the Uleå River, asserts too that these have come from the shores of Prussia and Pomerania. As hooks of this kind are not used in any other part of the Baltic or outside of it, it is evident that the salmon must have brought these from the above-mentioned places to the shores of the Gulf of Bothnia.

It is, on the other hand, but seldom that hooks of iron and tin are found in salmon in our rivers, which is caused, I believe, by the circumstance that the Scandinavians use far stronger lines for salmon-fishing than the Germans. I have, however, two in my possession which are of the exact kind used by fishermen in the sea about Bornholm and the south-east coast of Sweden.

Besides the above-mentioned kinds of hooks I have obtained a very peculiar one taken from a salmon off the town of Kristinestad. It is 4 cm. long, of hammered thick brass wire, and of a very uncommon shape, and through two holes fastened to two double-twined brass wires 40 cm. long, and 1 mm. thick. I do not know from what part of the Baltic this strange hook hails, but I believe from the Russian shore of the same.

The discovery of hooks of a foreign shape in salmon in the northern rivers of Sweden and Finland was made about 200 years ago, as may be seen in the journals of the Swedish Academy of Sciences of the seventeenth century, and even at that date their remarkable shape and manufacture attracted attention.

The relatively great number of brass hooks found in salmon taken in the rivers around the Gulf of Bothnia demonstrates beyond doubt that the fish, after visiting the coast of Northern Germany, return to the northernmost shores of Sweden and Finland, while some have visited the southern part of Sweden on their way north, as the iron hooks clearly indicate. If it is true, as is generally believed, that the salmon returns for spawning to the rivers of its birth, we may with equal force assume that the great takes of young salmon on the southern coast of Sweden and the shores of Baltic Germany during recent years is due to the rigid closing in of the rivers of Northern Sweden and Finland, whence they migrate south. During the last fifteen years, since when closing began in the Finnish rivers, the takes of young salmon—from 1 lb. to 2 lb. in weight—in nets about Bornholm and on the shores of Germany, have fabulously increased, and my opinion is that these fisheries are of such a destructive nature to this noble fish in Sweden and Finland that some arrangement ought to be made between the Baltic Powers to put a stop to the same.

By marking the salmon in England and Scotland, pisciculturists have come to the conclusion that varieties of salmon during their stay in salt water visit preferably certain parts of the coast for their food; thus, according to the late Frank Buckland, the shores around Yarmouth are the favourite haunts of the "bull-trout" of certain English and Scottish rivers. The great student of the salmon fisheries of Scotland, particularly those of the River Tweed, David Milne Holme, relates as an example of how quickly fish of the salmon kind can travel to a favourite feeding-ground, that a "bull-trout" marked with a silver thread with an inscription in the River Tweed, on March 29, 1852, was taken, on April 2, near Yarmouth, having thus accomplished a distance of nearly 300 miles in four days. Another fish was marked in the same river on March 10, 1880, and was caught at Yarmouth on May 5, having taken fifty-five days for the journey.

As the salmon, *Salmo salar*, according to the experience gained in Scotland, prefers sandy feeding-grounds during its stay in salt water, and as the bottom of the Baltic on the coast between Memel and Rügen, at Bornholm and South-East Sweden, is sand at a certain depth, where its favourite food is found, the cause of the migrations of the salmon in the Baltic southwards may be accounted for, while their return to the northern rivers of Sweden and Finland in the spring is unquestionably due to their breeding-instincts.

Helsingfors AND. JOH. MALMGREN

THE BRITISH ASSOCIATION

REPORTS

Report of the Committee, consisting of Major-Gen. Sir A. Clarke, R.E., C.B., Sir J. N. Douglass, Capt. Sir F. J. O. Evans, R.N., K.C.B., F.R.S., Capt. J. Parsons, R.N., Prof. J. Prestwich, F.R.S., Capt. W. J. L. Wharton, R.N., Messrs. E. Easton, R. B. Grantham, J. B. Redman, J. S. Valentine, L. F. Vernon-Harcourt, W. Whitaker, and J. W. Woodall, with C. E. De Rance and W. Topley as Secretaries, appointed for the Purpose of Inquiring into the Rate of Erosion of the Sea-coasts of England and Wales, and the Influence of the Artificial Abstraction of Shingle or other Material on that Action. Drawn up by C. E. De Rance and W. Topley.—The importance of the subject referred to this Committee for investigation is universally admitted, and the urgent need for inquiry is apparent to all who have any acquaintance with the changes which are in progress around our coasts. The subject is a large one, and can only be successfully attacked by many observers, working with a common purpose and upon some uniform plan. The Committee has been enlarged by the addition of some members who, by official position or special studies, are well able to assist in the work. In order fully to appreciate the influence, direct or indirect, of human agency in modifying the coast-line, it is necessary to be well acquainted with the natural conditions which prevail in the places referred to. The main features as regards most of the east and south-east coasts of England are well known; but even here there are probably local peculiarities not recorded in published works. Of the west coasts much less is known. It has therefore been thought desirable to ask for information upon many elementary points which, at first sight, do not appear necessary for the inquiry with which this Committee is intrusted. A shingle-beach is the natural protection of a coast; the erosion of a sea-cliff which has a bank of shingle in front of it is a very slow process. But if the shingle be removed the erosion goes on rapidly. This removal may take place in various ways. Changes in the natural distribution of the shingle may take place, the reasons for which are not always at present understood; upon this point we hope to obtain much information. More often, however, the movement is directly due to artificial causes. As a rule, the shingle travels along the shore in definite directions. If by any means the shingle is arrested at any one spot, the coast-line beyond that is left more or less bare of shingle. In the majority of cases such arresting of shingle is caused by building out "groynes," or by the construction of piers and harbour-mouths which act as large groynes. Ordinary groynes are built for the purpose of stopping the travelling of the shingle at certain places, with the object of preventing the loss of land by coast-erosion at those places. They are often built with a reckless disregard of the consequences which must necessarily follow to the coast thus robbed of its natural supply of shingle. Sometimes, however, the groynes fail in the purpose for which they are intended—by collecting an insufficient amount of shingle, by collecting it in the wrong places, or from other causes. These, again, are points upon which much valuable information may be obtained. Sometimes the decrease of shingle is due to a quantity being taken away from the beach for ballast, building, road-making, or other purposes. Solid rocks, or numerous large boulders, occurring between tide-marks, are also important protectors of the coast-line. In some cases these have been removed, and the waves have thus obtained a greater power over the land. To investigate these various points

is the main object of the Committee. A large amount of information is already in hand, much of which has been supplied by Mr. J. B. Redman, who for many years has devoted special attention to this subject. Mr. R. B. Grantham has also made important contributions respecting parts of the south-eastern coasts. But this information necessarily consists largely of local details, and it has been thought better to defer the publication of this for another year. Meanwhile the information referring to special districts will be made more complete, and general deductions may be more safely made. As far as possible the information obtained will be recorded upon the six-inch maps of the Ordnance Survey. These give with great accuracy the condition of the coast, and the position of every groyne, at the time when the survey was made.

Appended is a copy of the questions circulated. The Committee will be glad of assistance, from those whose local knowledge enables them to answer the questions, respecting any part of the coast-line of England and Wales. Copies of the forms for answering the questions can be had on application to the Secretaries.

Appendix—Copy of Questions.—1. What part of the English or Welsh coast do you know well? 2. What is the nature of that coast? (*a*) if cliffy, of what are the cliffs composed? (*b*) what are the heights of the cliff above H.W.M.? Greatest, average, least. 3. What is the direction of the coast-line? 4. What is the prevailing wind? 5. What wind is the most important—(*a*) in raising high waves? (*b*) in piling up shingle? (*c*) in the travelling of shingle? 6. What is the set of the tidal currents? 7. What is the range of tide? Vertical in feet, width in yards between high and low water, at spring tide, and at neap tide. 8. Does the area covered by the tide consist of bare rock, shingle, sand, or mud? (*a*) its mean and greatest breadth; (*b*) its distribution with respect to tide-mark; (*c*) the direction in which it travels; (*d*) the greatest size of the pebbles; (*e*) whether the shingle forms one continuous slope, or whether there is a "spring full" and "neap full," if the latter, state their heights above the respective tide-marks. 10. Is the shingle accumulating or diminishing, and at what rate? 11. If diminishing, is this due partly or entirely to artificial abstraction (*see* No. 13)? 12. If groynes are employed to arrest the travel of the shingle, state—(*a*) their direction with respect to the shore-line at that point; (*b*) their length; (*c*) their distance apart; (*d*) their height—(1) when built, (2) to leeward above the shingle, (3) to windward above the shingle; (*e*) the material of which they are built; (*f*) the influence which they exert. 13. If shingle, sand, or rock is being artificially removed, state—(*a*) from what part of the foreshore (with respect to the tidal range) the material is mainly taken; (*b*) for what purpose; (*c*) by whom—private individuals, local authorities, public companies; (*d*) whether half-tide reefs had, before such removal, acted as natural breakwaters. 14. Is the coast being worn back by the sea? If so, state—(*a*) at what special points or districts; (*b*) the nature and height of the cliffs at those places; (*c*) at what rate the erosion now takes place; (*d*) what data there may be for determining the rate from early maps or other documents; (*e*) is such loss confined to areas bare of shingle? 15. Is the bareness of shingle at any of these places due to artificial causes? (*a*) by abstraction of shingle; (*b*) by the erection of groynes, and the arresting of shingle elsewhere. 16. Apart from the increase of land by increase of shingle, is any land being gained from the sea? If so, state—(*a*) from what cause, as embanking salt-marsh or tidal foreshore; (*b*) the area so regained, and from what date. 17. Are there "dunes" of blown sand in your district? If so, state—(*a*) the name by which they are locally known; (*b*) their mean and greatest height; (*c*) their relation to river mouths and to areas of shingle; (*d*) if they are now increasing; (*e*) if they blow over the land, or are prevented from doing so by "bent grass" or other vegetation, or by water channels. 18. Mention any reports, papers, maps, or newspaper articles that have appeared upon this question bearing upon your district (copies will be thankfully received by the Secretaries). 19. Remarks bearing on the subject that may not seem covered by the foregoing questions. [N.B.—Answers to the foregoing questions will in most cases be rendered more precise and valuable by sketches illustrating the points referred to.]

SECTION A—Mathematical and Physical Science

On Loss of Heat by Radiation and Convection as affected by the Dimensions of the Cooling Body; and on Cooling in Vacuum, by J. T. Bottomley.—In the course of a series of experiments on the heating of conductors by the electric current, which were carried on during the past winter, I obtained a considerable number of results which both gave me the means of calculating the *emissivity* for heat in absolute measure of various surfaces under different circumstances, and also caused me to undertake a number of special experiments on the subject. These experiments are still in progress, and I am making preparation for a more extended and complete series; but a brief notice of some of the results already arrived at may not be without interest to the British Association.

The experiments were made on wires of various sizes, some of them covered and some of them bare, cooling in air at ordinary temperatures, and at normal and also at very much reduced pressures.

The mode of experimenting was as follows;—

A current passing through a wire generates heat, the amount of which is given by Joule's well-known law—

$$H = C^2 R/J \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where C is the current, R the electrical resistance, J Joule's equivalent, and H the quantity of heat generated per unit of time; each being reckoned in C.G.S. units. Let l be the length of the wire, d its diameter, and σ_t the specific resistance of the material at temperature $t°$ (at which temperature let us suppose that the wire in the given external conditions is maintained by the current). Then

$$R = \frac{\sigma_t l}{\frac{1}{4}\pi d^2} = \frac{4\sigma_t l}{\pi d^2}$$

Hence from (1)—

$$H = \frac{C^2}{J} \cdot \frac{4\sigma_t l}{\pi d^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Consider, now, that the wire suspended in the air is losing heat by its surface, and let us suppose that it neither loses nor gains heat by its ends. Let H' be the quantity lost by emission from the surface per unit of time. Let e be the emissivity, or quantity of heat lost per unit time per unit area of the cooling surface per unit difference of temperatures between the cooling surface and the surroundings; and $t°$ being, as has been said above, the temperature of the wire, let θ be the temperature of the surroundings. Then

$$H' = \pi d l \, . \, e \, . \, (t - \theta) \quad . \quad . \quad . \quad . \quad . \quad (3)$$

But when the wire has acquired a permanent temperature, with the current flowing through it, there is as much heat being lost at the sides as is being generated by the current. In this case $H = H'$; and we obtain the expression for e—

$$e = \frac{4 C^2 \sigma_t}{J \pi^2 d^3 (t - \theta)} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

My experiments consist in measuring the strength of the current and the temperature of the wire, the latter being effected by measuring the electric resistance of a known length of the wire while the current is flowing through it, and hence inferring the temperature. These being known, and likewise the temperature of the surroundings, we have all the data for finding e, the emissivity of the surface in absolute measure. The experiments of Mr. D. Macfarlane giving emissivities in absolute measure are well known, and are of undoubted accuracy. They were communicated to the Royal Society (*Proc.* Roy. Soc., 1872, p. 93); and the results are quoted in Prof. Everett's "Units and Physical Constants" (chap. ix. § 137). These experiments were made with a copper globe about 4 cm. in diameter, suspended in a cylindrical chamber, with top and bottom, about 60 cm. in diameter, and 60 cm. high. The results may be briefly summed up as follows:—

Macfarlane finds an emissivity of about 1/4000th of the thermal unit C.G.S. per square centimetre per second per degree of difference of temperatures between cooling body and surroundings for a polished surface, with an excess of temperature of a little more than 60° C.; and, for a blackened surface, the same emissivity with an excess of 5° C. or under.

Using round wires of small diameter (0·85 mm. and under), and with the surfaces either brightly polished or in common dull condition of a wire fresh from the maker, I have found a much larger emissivity than 1/4000. I have obtained different values of e for wires of different sizes, varying from 1/2000 down to 1/400, which was obtained with a wire of 0·40 mm. diameter, and with an excess of temperature of 24° C. It seems to be shown by all the experiments I have made that, other things being the same, the smaller the wire the greater the emissivity.

To do away with the part of the emissivity which is due to convection and conduction by the air, I have commenced experiments on loss of heat by small wires in the nearly perfect vacuum afforded by the modern mercurial air-pump. This part of the subject was experimented on long ago by Dulong and Petit, and within the last few years by Winkelman and Kundt and Warburg; lastly, and much more perfectly, by Mr. Crookes (*Proc.* Roy. Soc., vol. xxxi. p. 239), though in no case, I believe, were the emissivities in absolute measure determined. The conclusion come to by all these experimenters is the same, namely, that there is a decrease of emissivity due to lowering of the air-pressure, this decrease being very small for a reduction down to one-half or one-third of the ordinary atmospheric pressure, but becoming very great as the vacuum approaches completeness.

The very interesting experiments of Mr. Crookes seem to show that, even with the high vacuum which he obtained, the effect of the residual gas in carrying off heat from the cooling body was far from being annulled.

The following table shows the emissivity of a copper wire with bright surface half a metre long, 0·40 mm. in diameter, and sealed into a glass tube about 1·5 cm. in internal diameter:—

Current, amperes	Pressure, 760 millims.		Pressure, 380 millims.		Pressure, 180 millims.		
4·7	1/1822	4·5	1/1784	5·5	1/2176	17	1/6443
22·5	1/2084	21·5	1/1996	23·5	1/2174	68	1/5620
56	1/2114	58	1/2180	55	1/2082		1/4606[1]

The following table may also be found interesting. It shows the emissivity in absolute measure of some materials commonly used as insulating coverings for wires.

Specifying number B.W.G. and nature of covering	Length of wire. Centims.	Resistance of 100 centims. B.A. units	Diameter of wire in millims.	Diameter of covered wire, outside measurement	$t-\theta$	Emissivity

On Some Phenomena Connected with Iron and other Metals in the Solid and Molten States, with Notes of Experiments, by W. J. Millar, C.E., Sec. Inst. Engineers and Shipbuilders in Scotland.—1, *Object of Paper.*—Results of experiments by the author with various metals, such as cast-iron, gun-metal, phosphor-bronze, lead, copper, and type-metal. The object being to determine the cause of the well-known phenomena of the flotation of cold cast-iron on molten cast-iron, and as to whether any expansion took place upon solidification in the metals above noted. 2. Notes of some of the experiments from which the author concludes that the cause of flotation of the solid metal on liquid metal of the same kind is *buoyancy*, due to expansion suddenly set up in the immersed pieces, and that this expansion was found by careful measurement to be at least equal to the shrinkage or total decrease in length of the piece from white hot solid to finally cooled down solid. Further, that the expansion observed is obtained within much lower limits of temperature than the shrinkage; as the pieces, which were in all cases removed from the molten metal, immediately on appearing floating hardly showed redness, and when broken it was found that the crystalline character of the metal remained. 3. Notes of experiments made by gradually heating pieces of cast-iron—the results of all these experiments leading the author to conclude that the *rate* of expansion in cast-iron is at first much more rapid at low temperature than afterwards at high temperature. 4. From experiments carried on with pieces of lead and copper and type-metal, it was found that if any flotation occurred it was only with small light pieces—heavy pieces sinking and remaining at bottom of ladle. Gun-metal and phosphor-bronze behaved like cast-iron. 5. Consideration of the peculiar appearance, or "*break*," observed on the surface of molten cast-iron, the figures presenting a geometrical pattern, like interlacing circles or stars. The author believes that this appearance is due to cracks forming upon the rapidly forming skin—these cracks taking more or less a circular form from the convex forms into which the various parts of the surface are thrown, due to the bubbling up of gas or air. This appearance is limited to cast-iron, and experienced observers can tell the quality of the iron from the form of pattern or figures showing on the molten surface. 6. From observation and experiments carried out from time to time, the author concludes that no perceptible increase of volume of the metals noted occurs at the moment of solidification; at least when free from air or gas confined within the casting.

[1] Temperature probably much too low. The wire, sagging down, touched the inside of the glass tube in several points.

On a Gyrostatic Working Model of the Magnetic Compass, by Sir William Thomson.—In my communication to the British Association at Southport,[1] I explained several methods for overcoming the difficulties which had rendered nugatory, I [illegible] all previous attempts to realise Foucault's beautiful idea [illegible] covering with perfect definiteness the earth's rotational motion by means of the gyroscope. One of these, which I had actually myself put in practice with partially satisfactory results, was a

Gyrostatic Balance for Measuring the Vertical Component of the Earth's Rotation.

It consisted of one of my gyrostats supported on knife-edges attached to its containing case, with their line perpendicular to the axis of the interior fly-wheel and above the centre of gravity of the fly-wheel and framework by an exceedingly small height, when the framework is held with the axis of the fly-wheel and the line of knife-edges both horizontal, and the knife-edges downwards in proper position for performing their function. The apparatus, when supported on its knife-edges with the fly-wheel not spinning, may be dealt with as the beam of an ordinary balance. Let now the framework bear two small knife-edges, or knife-edged holes, like those of the beam of an ordinary balance, giving bearing-points for weights in a line, cutting the line of the knife-edges as nearly as possible, and of course (unless there is rea on to the contrary in the shape of the framework) approximately perpendicular to this line, and, for convenience of putting on and off weights, hang, as in an ordinary balance, two very light pans by hooks on these edges in the usual way. Now, with the fly-wheel not running, adjust by weights in the pans if necessary, so that the framework rests in equilibrium in a certain marked position with the axis of rotation inclined slightly to the horizontal, in order that the axis of the fly-wheel, whether spinning or at rest, may always slip down so as to press on one and not on the other of the two end plates belonging to its two ends. Now, unhook the pans and take away the gyrostat and spin it; replace it on its knife-edges, hang on the two pans, and find the weight required to balance it in the marked position with the fly-wheel now rotating rapidly. This weight, by an obvious formula which was placed before the Section at Southport, gives an accurate measure of the vertical component of the earth's rotation.[2]

Gyrostatic Model of the Dipping Needle

I also showed at Southport that the gyrostatic balance described above, if modified by fixing the knife-edges, with their line passing as accurately as possible through the centre of gravity of the fly-wheel and framework, and with the faces of the knives so placed that they shall perform their function properly when the axis of the fly-wheel is parallel to the earth's axis of rotation, and the rotation of the fly-wheel in the same direction as the earth's, will act just as does an ordinary magnetic dipping needle; but showing latitude instead of dip, and dipping the south end of the axis downwards instead of the end that is

[1] No report of this communication has, so far as I know, hitherto appeared in print.

[2] The formula is

$$gw = \frac{1}{a} W k^2 \omega \gamma \sin l;$$

where w denotes the balancing weight; gw the force of gravity upon it; a the arm on which this force acts; W the weight of the fly-wheel; k its radius of gyration; ω its angular velocity; γ the earth's angular velocity; and l the latitude of the place.

towards the north as does the magnetic dipping needle. Thus, if the bearing of the knife-edges be placed east and west, the gyrostat will balance with its axis parallel to the earth's axis, and therefore dipping with its south end downwards in northern latitudes and its north end downwards in southern latitudes. If displaced from this position and left to itself, it will oscillate according to precisely the same law as that by which the magnetic needle oscillates. If the bearings be turned round in azimuth, the position of equilibrium will follow the same law as does that of a magnetic dipping needle similarly dealt with. Thus, if the line of knife-edges be north and south, the gyrostat will balance with the axis of the fly-wheel vertical, and if displaced from this position will oscillate still according to the same law; but with directive couple equal to the sine of the latitude into the directive couple experienced when the line of knife-edges is east and west. Thus this piece of apparatus gives us the means of definitely measuring the direction of the earth's rotation, and the angular velocity of the rotation. These experiments will, I believe, be very easily performed, although I have not myself hitherto found time to try them.

Gyrostatic Model of a Magnetic Compass

At Southport I showed that a gyrostat supported frictionlessly on a fixed vertical axis, with the axis of the fly-wheel horizontal or nearly so, will act just as does the magnetic compass, but with reference to "astronomical north" (that is to say, rotational north) instead of "magnetic north." I also showed a method of mounting a gyrostat so as to leave it free to turn round a truly vertical axis, impeded by so little of frictional influence as not to prevent the realisation of the idea. The method, however, promised to be somewhat troublesome, and I have since found that the object of producing a gyrostatic model of the magnetic compass may, with a very remarkable dynamical modification, be much more simply attained by merely suspending the gyrostat by a very long, fine wire, or even by floating it with sufficient stability on a properly planned floater. To investigate the theory of this arrangement let us first suppose a gyrostat, with the axis of its fly-wheel horizontal, to be hung by a very fine wire attached to its framework at a point, as far as can conveniently be arranged for, above the centre of gravity of fly-wheel and framework, and let the upper end of the wire be attached to a torsion head, capable of being turned round a fixed vertical axis as in a Coulomb's torsion balance. First, for simplicity, let us suppose the earth to be not rotating. The fly-wheel being set into rapid rotation, let the gyrostat be hung by the wire, and after being steadied as carefully as possible by hand, let it be left to itself. If it be observed to commence turning azimuthally in either direction, check this motion by the torsion head; that is to say, turn the torsion head gently in a direction opposite to the observed azimuthal motion until this motion ceases. Then do nothing to the torsion head, and observe if a reverse azimuthal motion supervenes. If it does, check this motion also by opposing it by torsion, but more gently than before. Go on until when the torsion head is left untouched the gyrostat remains at rest. The process gone through will have been undistinguishable from what would have had to be performed if, instead of the gyrostat with its rotating fly-wheel, a rigid body of the same weight, but with much greater moment of inertia about the vertical axis, had been in its place. The formula for the augmented moment of inertia is as follows. Denote by—

W, the whole suspended weight of fly-wheel and framework;
K, the radius of gyration round the vertical through the centre of gravity of the whole mass regarded for a moment as one rigid body;
w, the mass of the fly-wheel;
k, the radius of gyration of the fly-wheel;
a, the distance of the point of attachment of the wire above the centre of gravity of fly-wheel and framework;
g, the force of gravity on unit mass;
ω, the angular velocity of the fly-wheel; the virtual moment of inertia round a vertical axis is

$$\mathrm{WK}^2\left(1 + \frac{w^2 k^4 \omega^2}{\mathrm{W}^2 \mathrm{K}^2 a g}\right). \qquad (1)$$

The proof is very easy. Here it is. Denote by—

ϕ, the angle between a fixed vertical plane and the vertical plane containing the axle of the fly-wheel at any time t;
θ, the angle (supposed to be infinitely small and in the plane of ϕ), at which the line a is inclined to the vertical at time t;
H, the moment of the torque round the vertical axis exerted by the bearing wire on the suspended fly-wheel and framework.

By the law of generation of moment of momentum round an axis perpendicular to the axis of rotation requisite to turn the axis of rotation with an angular velocity $d\phi/dt$, we have

$$wk^2\omega\frac{d\phi}{dt} = g\mathrm{W}a\theta \quad . \; . \; . \; . \; . \; . \; . \; . \quad (2)$$

because $g\mathrm{W}a\theta$ is the moment of the couple in the vertical plane through the axis by which the angular motion $d\phi/dt$ in the horizontal plane is produced. Again, by the same principle of generation of moment of momentum taken in connection with the elementary principle of acceleration of angular velocity, we have

$$wk^2\omega\frac{d\theta}{dt} + \mathrm{WK}^2\frac{d^2\phi}{dt^2} = \mathrm{H} \quad . \; . \; . \; . \quad (3)$$

Eliminating θ between these equations we find

$$\left(\frac{w^2 k^4 \omega^2}{g\mathrm{W}a} + \mathrm{WK}^2\right)\frac{d^2\phi}{dt^2} = \mathrm{H} \quad . \; . \; . \quad (4)$$

which proves that the action of H in generating azimuthal motion is the same as it would be if a single rigid body of moment of inertia given by the formula (1), as said above, were substituted for the gyrostat. Now to realise the gyrostatic model compass: arrange a gyrostat according to the preceding description with a very fine steel bearing wire, not less than 5 or 10 metres long (the longer the better; the loftiest sufficiently sheltered inclosure conveniently available should be chosen for the experiment). Proceed precisely as above to bring the gyrostat to rest by aid of the torsion head, attached to a beam of the roof or other convenient support sharing the earth's actual rotation. Suppose for a moment the locality of the experiment to be either the North or South Pole, the operation to be performed to bring the gyrostat to rest will not be discoverably different from what it was, as we first imagined it when the earth was supposed to be not rotating. The only difference will be that, when the gyrostat hangs at rest, relatively to the earth, θ will have a very small constant value; so small that the inclination of a to the vertical will be quite imperceptible, unless a were made so exceedingly small that the arrangement should give the result, to discover which was the object of the gyrostatic model balance described above; that is to say, to discover the vertical component of the earth's rotation. In reality we have made a as large as we conveniently can; and its inclination to the vertical will therefore be very small, when the moment of the tension of the wire round a horizontal axis perpendicular to the axis of rotation of the fly-wheel is just sufficient to cause the axis of the fly-wheel to turn round with the earth. Let now the locality be anywhere except at the North or South Pole; and now, instead of bringing the gyrostat to rest at random in any position, bring it to rest by successive trials in a position in which, judging by the torsion head and the position of the gyrostat, we see that there is no torsion of the wire. In this position the axis of the gyrostat will be in the north and south line, and, the equilibrium being stable, the direction of rotation of the fly-wheel must be the same as that of the compotent rotation of the earth round the north and south horizontal line, unless (which is a case to be avoided in practice) the torsional rigidity of the wire is so great as to convert into stability the instability which, with zero torsional rigidity, the rotational influence would produce in respect to the equilibrium of the gyrostat with its axis reversed from the position of gyrostatic stability. It may be remarked, however, that even though the torsional rigidity were so great that there were two stable positions with no twist, the position of gyrostatic unstable equilibrium made stable by torsion would not be that arrived at: the position of stable gyrostatic equilibrium, rendered more stable by torsion, would be the position arrived at, by the natural process of turning the torsion head always in the direction of finding by trial a position of stable equilibrium with the wire untwisted by manipulation of the torsion head. Now by manipulating the torsion head bring the gyrostat into equilibrium with its axis inclined at any angle, ϕ, to that position in which the bearing wire is untwisted; it will be found that the torque required to balance it in any oblique position will be proportional to the sin ϕ. The chief difficulty in realising this description results from the great augmentation of virtual moment of inertia, represented by the formula (1) above. The paper at present communicated to the Section contains calculations on this subject, which

throw light on many of the practical difficulties hitherto felt in any method of carrying out gyrostatic investigation of the earth's rotation, and which have led the author to fall back upon the method described by him at Southport, of which the essential characteristic is to constrain the frame of the gyrostat in such a manner as to leave it just one degree of freedom to move. The paper concludes with the description of a simplified manner of realising this condition for a gyrostatic compass—that is to say, a gyrostat free to rotate about an axis either rigorously or very approximately vertical.

SECTION C—GEOLOGY

On Ice-Age Theories, by Rev. E. Hill, M.A., F.G.S., Tutor of St. John's College, Cambridge.—On the Montreal Mountain, in the neighbouring quarries, at the mouth of the Saguenay River, and more or less everywhere over all Canada and all the north and north-west of this continent, are seen phenomena which imply a former vastly extended action of ice. The like are found over Europe and Asia, thus completely encircling the Pole. Many theories have been propounded to account for these facts. It is proposed to pass these before you in review. Any explanation ought to account not only for cold greater than the present, but for accumulations of snow and ice. A kindred phenomenon is the greater size of the Antarctic ice-cap. The supposed interglacial warm periods, and the unquestioned luxuriance of Miocene vegetation in Greenland, ought also to find their causes in any thoroughly satisfactory theory. The theories which have been propounded fall into three groups, as Cosmical, Terrestrial, and Astronomical (or Periodical). The Cosmical theories are Poisson's Cold-Space theory - incomprehensible; and the Cold-Sun theory of S. V. Wood and others—lacking any evidence. The Terrestrial theories are numerous. Lyell's suggestion of Polar-continent and Equatorial-ocean is opposed by evidence that continents and oceans lay on much the same areas as now. The contrary view, Polar-ocean and Equatorial-land, would deserve consideration but for the same opposing evidence. The elevation view (Dana, Wallace), which alleges greater altitude of mountain-chains, disagrees with the strong evidence for land-depression during the period. The submergence view of Dr. Dawson agrees with this evidence, but requires elucidation. Alteration of ocean-currents (Gunn, J. S. Gardiner) is a most powerful agency, but would act locally rather than universally round the Pole. Alteration of prevalent winds, hitherto worked out by no one, deserves attentive consideration. Conditions are conceivable which would produce over an area winds from cold quarters almost permanently. However, this seems open to the same objection as the preceding theory. Last come the Astronomical or Periodical theories. A tilt of the earth's axis was suggested by Belt, but suggested as owing to causes which are wholly insufficient. Tilting from astronomical agencies is slight, though its action would be in the direction required. Herschel suggested the Eccentricity theory, but abandoned it. Adhémar's Precession theory, as explained by himself, involved an absolute fallacy. The celebrated view of Dr. Croll combines the Precession and Eccentricity theories into one. It exactly agrees with the Antarctic greater extension of ice, and provides an explanation of interglacial warm periods. The great difficulty in its way is to see how a mere difference in distribution through the year of an unchanged total heat receipt can produce consequences so vast. The laws of radiation explain but a very minute part, the laws of evaporation perhaps rather more; but, so far as can at present be seen, both together are inadequate. Another serious objection is that the theory seems to require the climate of the northern hemisphere to be now in a state of change for the better, of which at present there appears no evidence. Dr. Croll's elaborate explanations of the reaction of one effect upon another—fogs, deflection of currents, and the like—have no special connection with his own theory. They would act in all cases, and support all theories equally. The arguments, if admitted, would only prove that the earth's climates are in a state of highly unstable equilibrium, in which a slight cause may produce an enormous change. Nor are his arguments universally admitted. In conclusion, Dr. Croll's theory seems inadequate: alteration of currents and winds are the most powerful causes suggested hitherto: further investigations ought to be made as to the nature and extent of the last series of changes in the outlines of the continents of the globe.

What is a Mineral Vein or Lode? by C. Le Neve Foster, B.A., D.Sc., F.G.S., H.M. Inspector of Mines.—The author quoted briefly the definitions of a mineral vein given by Werner, Carne, Von Cotta, Grimm, Von Groddeck, Geikie, Sandberger, and Serlo, who, in common with most geologists, have looked upon mineral veins as "the contents of fissures." While admitting that a very large number of veins may be so described, the author contended that the exceptions are sufficiently important and numerous to warrant a change in the definition. He is of opinion that many of the principal and most productive tin-lodes in Cornwall are simply tabular masses of altered granite adjacent to fissures; and he brought forward the opinions of other geologists to show that certain veins in the English Lake district, the Tyrol, Nova Scotia, Nevada, Colorado, California, and Australia, are not filled-up fissures. In conclusion, he proposed the following definition: "A mineral vein or lode is a tabular mineral mass formed, more or less entirely, subsequently to the inclosing rocks."

The Acadian Basin in American Geology, by L. W. Bailey, Geological Survey of Canada.—The Acadian Basin, embracing the region bordering on and including the Gulf of St. Lawrence, together with the provinces of New Brunswick, Nova Scotia, Newfoundland, and Prince Edward Island, constitutes one of the natural physical divisions of the continent of North America, and exhibits many marked peculiarities of climate and floral and faunal distribution. In its geological structure, and in the history which this reveals, its individuality is not less clearly marked, being often in strong contrast with that of other portions of the continent farther west; and in some periods and features even exhibiting a closer relationship with the geology of Europe. In the present paper, the facts bearing upon this individuality are summarised and discussed; including the consideration of the varying land-surfaces of Acadia in different eras, the time and nature of its physical movements, its climate, and its life. A review of recent progress in the investigation of its geological structure is also given.

Upon the Improbability of the Theory that former Glacial Periods in the Northern Hemisphere were due to Eccentricity of the Earth's Orbit, and to its Winter Perihelion in the North, by W. F. Stanley, F.G.S., F.R.Met.S.—The theory of Dr. Croll, accepted by many geologists, is that former glacial periods in the northern hemisphere were due to greater eccentricity of the earth's orbit, and to this hemisphere being at the time of glaciation in winter perihelion. This theory is supported upon conditions that are stated to rule approximately at the present time in the southern hemisphere, which is assumed to be the colder. Recent researches by Ferrel and Dr. Hann, with the aid of temperature observations taken by the recent Transit of Venus expeditions, have shown that the mean temperature of the southern hemisphere is equal to, if not higher than the northern, the proportions being 15·4 southern and 15·3 northern. The conditions that rule in the south at the present time are a limited frozen area about the South Pole, not exceeding the sixtieth parallel of latitude; whereas in the north frozen ground in certain districts, as in Siberia and North-Western Canada, extends beyond the fiftieth parallel; therefore by comparison the north, as regards the latitude in which Great Britain is situated, is at present the most glaciated hemisphere. As it is very difficult to conceive that the earth had at any former period a lower initial temperature, or that the sun possessed less heating power, glaciation in the north could never have depended upon the conditions argued in Dr. Croll's theory. The author suggested that glaciation within latitudes between 40° to 60° was probably at all periods a local phenomenon depending upon the direction taken by aerial and oceanic currents; as, for instance, Greenland is at present glaciated, Norway has a mild climate in the same latitude, the one being situated in the predominating northern Atlantic currents, the other in the southern. Certain physical changes suggested in the distribution of land would reverse these conditions and render Greenland the warmer climate, Norway the colder.

On the Occurrence of the Norwegian "Apatitbringer" in Canada, with a few Notes on the Microscopic Characters of some Laurentian Amphibolites, by Frank D. Adams, M.Ap.Sc., Assistant Chemist and Lithologist to the Geological Survey of Canada.—The paper first gives a short account of the investigations which have been made on this amphibole-scapolite rock in Norway, where all the principal deposits of apatite either traverse it or occur in its immediate vicinity. The deposits of apatite in Canada generally occur associated with some variety of highly pyroxenic rock, often holding orthoclase and quartz. The "Apatitbringer" has, however, recently been found in the

vicinity of the town of Arnprior on the River Ottawa. It closely resembles the Norwegian rock, both in external appearance and in its microscopic characters, containing hornblende, scapolite, and pyroxene as essential constituents. A number of amphibolites in the Museum of the Geological Survey of Canada, which resemble this rock in appearance, have been sliced and examined with the microscope, and one of them found to contain scapolite in large amount. It was collected at Mazinaw Lake, in the township of Abinger, and is from the same belt of hornblendic rocks as that in which Arnprior is situated. The paper closes with a short account of some of these amphibolites.

The Geological Age of the Acadian Fauna, by G. F. Matthew, A.M., F.R.S.C.—In this sketch an attempt is made, by comparison with the Cambrian fauna of other countries, and especially of Wales, to fix more exactly than has hitherto been done the position of the assemblage of organisms found near the base of the St. John group. The trilobites are taken as a criterion for this purpose. A brief statement of the position and thickness of the beds is given, showing the relation of the fauna to the formation as a whole. It is shown that the genera and species of the Acadian trilobites do not agree with those of the Menevian, in the restricted application of that term now in vogue; the great *Paradoxides* with short eyelobes, and the genera *Anopolenus*, *Agraulos* (= *Arionellus*), *Erinnys*, and *Holocephalina* being, so far as known, absent from it. On the other hand, it shows very close relationships in its genera to the Solva group fauna, especially in the following species:—

Solva Group	Acadian Fauna
Conocoryphe solvensis, Hicks	*Ctenocephalus matthewi*, Hartt sp.
Conocoryphe bufo, Hicks	*Conocoryphe elegans*, Hartt sp.
Paradoxides harknessi, Hicks	*Paradoxides eteminicus*, Matthew

As bearing on the question of the age of the Acadian fauna, the development of the eyelobe in *Paradoxides* is referred to, and it is shown that while in the Cambrian rocks of Wales the length of the eyelobe is in direct relation to the age of the strata, the *Paradoxides* of the Acadian fauna, having continuous or nearly continuous eyelobes, are more primitive in their facies than those of the Menevian, and agree with the species found in the Solva group. The family of Conocoryphidæ, restricting the name to such species as those described by Corda under *Conocoryphe* and *Ctenocephalus*, are a marked feature of this early fauna; and *Conocoryphe* has a characteristic suture not observed in the Menevian genera. The Acadian *Ctenocephalus* also differs in this respect from the Bohemian species.

On the More Ancient Land Floras of the Old and New Worlds, by Principal Dawson, LL.D., F.R.S.—In the Laurentian period vegetable life is probably indicated, on both sides of the Atlantic, by the deposits of graphite found in certain horizons. There is good evidence of the existence of land at the time when these graphitic beds were deposited, but no direct evidence as yet of land plants. The carbon of these beds might have been wholly from subaquatic vegetation; but there is no certainty that it may not have been in part of terrestrial origin, and there are perhaps some chemical arguments in favour of this. The solution of the question depends on the possible discovery of unaltered Laurentian sediments. The Silurian land flora, so far as known, is meagre. The fact that *Eopteris* has been found to be merely a film of pyrite deprives us of the ferns. There remain some verticillately-leaved plants allied to *Annularia*, the humble Acrogens of the genus *Psilophyton*, and the somewhat enigmatical plants of the genera *Pachytheca*, *Prototaxites*, and *Berwynia*, with some uncertain Lycopods. We have thus at least forerunners of the families of the *Asterophyllitæ*, the *Lycopodiaceæ*, and the *Coniferæ*. The comparison of the rich Devonian or Erian flora of the two sides of the Atlantic is very interesting. On both continents it presents three phases—those of the Lower, Middle, and Upper Erian—and there is a remarkable correspondence of these in countries so wide apart as Scotland, Belgium, Canada, Brazil, and Australia. Examples of this were given in the Rhizocarps, at this period very important, in the Lycopods, the Equisetaceæ, the Ferns, and the Conifers. The number of coniferous trees belonging to *Dadoxylon* and allied genera, and the abundance of ferns, often arborescent, were especial features in the Middle and Later Erian. The flora of the Erian age culminated and then diminished. In like manner that of the succeeding Carboniferous period had a small commencement quite distinct in its species from the Erian; it culminated in the rich vegetation of the true coal formation, which was remarkably similar over the whole world, presenting, however, some curious local differences and dividing lines which are beginning to become more manifest as discovery proceeds. In the Upper Carboniferous the flora diminishes in richness, and the Permian age is, so far as known, one of decadence rather than of new forms. Great progress has recently been made by Williamson and others in unravelling the affinities of the coal-formation plants, and we are on the eve of great discoveries in this field. Throughout the Silurian the conditions do not seem to have been eminently favourable to plants, but the few forms known indicate two types of Acrogens, and one leading to the Gymnosperms, and there is no reason to doubt the existence of insular land richly clothed at least with the few forms of vegetation known to have existed. In the Erian and Carboniferous there seem to have been two great waves of plant-life, proceeding over the continents from the north, and separated by an interval of comparative sterility. But no very material advance was made in them, so that the flora of the whole Palæozoic period presents a great unity and even monotony of forms, and is very distinct from that of succeeding times. Still the leading families of the *Rhizocarpeæ*, *Equisetaceæ*, *Lycopodiaceæ*, *Filices*, and *Coniferæ*, established in Palæozoic times, still remain; and the changes which have occurred consist mainly in the degradation of the three first-named families, and in the introduction of new types of Gymnosperms and Phænogams. These changes, delayed and scarcely perceptible in the Permian and Early Mesozoic, seem to have been greatly accelerated in the Later Mesozoic.

On the Structure of English and American Carboniferous Coals, by Edward Wethered, F.G.S., F.C.S.—The author had examined several seams of coal from England and America. He pointed out that they were not always made up of one continuous bed of coal, but often comprised several distinct beds. In the case of the well-known Welsh "four-feet" seam there were four distinct strata of coals, separated by clay beds of a few inches thick. In the case of the "splint coal" from Whitehill Colliery, near Edinburgh, the seam presented three clearly-defined beds of coal, but these were not separated by partings of any kind. With a view of testing the "Spore theory" of the origin of coal, as propounded by Prof. Huxley, the author had obtained a portion of the "better-bed" seam intact for a thickness of 10 inches from the top. He had examined this inch by inch, by preparing thirty-three microscopic sections. At the top were $3\frac{1}{2}$ inches of dull lustrous coal, termed "laminated coal." This the author found to be practically a mass of macrospores and microspores. Below this there was a change in the character of the seam. Spores became less numerous; in places they were scarce, the mass being made up of vegetable tissue and a substance to which the author gives the term "hydrocarbon." He could not, therefore, support Prof. Huxley in saying that the "better-bed" coal was "simply the sporangia and spore-cases of plants." The assertion would, however, apply to the first $3\frac{1}{2}$ inches of the seam. The "splint coal" from Whitehill Colliery was a better example of a spore coal than the "better-bed." The bottom stratum was 4 inches thick, and presented a dull lustre, with thin bright layers traversing at intervals. The dull portion was a mass of spores and spore-cases, but these did not enter the bright layers. A vertical section cutting a bright layer, bounded on either side by dull lustrous coal, showed plenty of spores in the dull coal, but in the bright not one was detected. The second bed in this seam was 1 foot thick; it was of a brighter lustre than the 4 inches below, but two layers could be distinctly made out, one more lustrous than the other. In the dullest of the two, spores were found, which, however, were less numerous than in the bed below, and were also of a different variety. In the bright layers the spores were absent. The top bed of the seam was also 1 foot thick, and might be defined as a mass of spores, chiefly microspores, except in the bright layers. The American coals examined were collected by the author from the Warrior Coalfields of Alabama, and from near Pittsburg, Pennsylvania. The same structural affinities were noticed as in the English coals, and the author therefore came to the conclusion that the English and American Carboniferous coals had a common origin. The spores in the coal from both countries were closely allied. Some microspores from Alabama were identical with those which occur in the lower bed of the Welsh "four-feet" seam. A feature in spores obtained from all the coals was the triradiate markings which they exhibited. Whether this was to be regarded as superficial or not, it was very characteristic of them, and was therefore to be considered in attempting to ally them with modern vegetation. The

author regarded peat in the light of post-Tertiary coal; lignite as peat in a transition state to coal; and coal as the remains of Carboniferous bogs. The author referred to the practical application of a knowledge of the microscopic structure of coal, as enabling an expert to judge of the nature of a coal from an examination of it with a pocket lens.

Points of Dissimilarity and Resemblance between Acadian and Scottish Glacial Beds, by Ralph Richardson, F.R.S.E., V.P. G.S.Edinb.—Mr. Richardson said that, in his "Acadian Geology," Principal Dawson gave the following as a typical section of the superficial geology of Acadia—that is, Nova Scotia, New Brunswick, and Prince Edward Island—and as, in some respects, also applicable to Canada and Maine, viz.: At the bottom, peaty deposits; then unstratified Boulder Clay; then stratified Leda Clay, indicating deep water; and, lastly, gravel and sand beds, the Saxicava sand indicating shallow water. Mr. Richardson pointed out wherein such a section differed from and resembled the glacial beds of Scotland. He said the latter showed no such orderly arrangement as the Acadian, and could not, as a rule, be divided into deep and shallow water-beds. The marine shells in the Scottish beds are all mixed up together, regardless, as a rule, of the province—whether Arctic or British, or both—to which they properly belong, regardless of the depths which they usually tenant, and regardless of the deposit (whether clay, gravel, or sand) in which they are now found fossil. They are likewise met with at all heights, from the level of the sea to more than 500 feet above it. No system of dispersion of boulder-erratics from definite centres in Scotland seems as yet ascertained. The peaty deposits, occurring in Principal Dawson's section *below* the Boulder Clay or till, occur in Scotland above it. With regard to points of resemblance, the facies of the shells in Acadia and Scotland is similar, being of the Arctic and British-Arctic type. Again, both in Acadia and Scotland, all the fossiliferous glacial beds occur above the unstratified Boulder Clay or till. Mr. Richardson cited various Scottish sections to prove this, and remarked that the belief in earlier and later Boulder Clays is of long standing in Scotland. He concluded by pointing out that, in their cardinal features, the Acadian and Scottish glacial beds seemed to coincide. In both Acadia and Scotland that great mass of unstratified clay known as *till* existed; and doubtless the geologists of the New World were, like those of the Old, puzzled to account for its origin with certainty and satisfaction. The question was left unsolved by the meeting of the British Association in Edinburgh in 1850; although then discussed by Hugh Miller and Prof. John Fleming. The author hoped that during the present meeting some advance would be made in solving this great problem, as well as in correlating and arranging the glacial beds of Canada, Acadia, and Britain.

On the Mode of Occurrence of Precious Stones and Metals in India, by V. Ball, M.A., F.R.S.—For full 3000 years India has been known as the source of precious stones and metals, but scarcely 200 years have elapsed since other countries yielding precious stones have entered into competition with her; and it is only within the present century that she has ceased to hold a pre-eminent position as a supplier of the markets of the world. In order to arrive at a full and satisfactory elucidation of this subject, two branches of inquiry must be undertaken—one based upon what has been actually ascertained by careful geological exploration of the country, and the other upon such historical records as are available of the former production of the minerals in question, and of the indications of the sites where they were mined. By means of our present knowledge of the geology, it has become possible to give definite form to many vague statements by early writers, and to recognise the actual positions of mines which are now, by the people of the localities themselves, forgotten and deserted. In the majority of these cases, had the geologist not got the historical hand to guide him, he would be unwilling to predicate the presence of such minerals from mere superficial examination. As a collateral result, many of the widespread myths and fables connected with mining have proved to have originated in peculiar local customs. They rest, therefore, on more substantial bases of facts than could have been suspected by any one unacquainted with these customs. This method of combining the results of geological research with historical records the author has found on previous occasions to have the advantage of bringing the geologist into touch with the rest of humanity, arranging as it does the interest of historians, linguists, and others, who find in the facts so presented to them pabulum applicable to the requirements of their own particular pursuits. In this paper it will not be necessary or suitable to enter at length into details—the author having done so elsewhere.[1] His object is rather to direct attention to the subject generally, and to make known the fact that much has been accomplished of late years which has not as yet found its way into manuals and encyclopædias. Most of the information to be found in such works is far behind our present knowledge; and, where not actually incorrect, has been superseded by fuller and more accurate observations. The subjects taken for special consideration are the following:—Diamond, ruby, sapphire, spinel, beryl, emerald, lapis-lazuli, gold, silver. The steel of India, or *wootz*, might be included here, since, at least 2000 years ago, it was one of the most precious productions of India.

On the Relative Ages of the American and the English Cretaceous and Eocene Series, by J. Starkie Gardner, F.L.S., F.G.S.—The paper is a contribution towards the determination of the ages of the American Cretaceo-Eocene rocks, relative to those of Europe. It briefly describes the chief characteristics of the various stages of the series in America. The lowest beds there are distinguished by the presence of well-developed dicotyledonous leaves, associated with *Ammonites* and other Cretaceous Mollusca, considered to warrant their correlation with the Gault and Chalk of England. Newer beds thought to be intermediate in age between Secondary and Tertiary are distinguished by the incoming of palms and a new flora of Dicotyledons, associated with *Mosasaurus*. The rest are correlated with the various divisions of the Tertiary series recognised in Europe. The entire series seems to have been deposited without any considerable break in continuity, but reveals a sudden transition from a temperate to a subtropical flora, and from a Cretaceous to a Tertiary Vertebrata. The high development of the flora is, however, quite irreconcilable with the accepted correlation. In further comparing the American series with that of Europe, it is observed that the subdivisions of the Cretaceous series were first determined for a limited area, when different ideas of evolution and gradual passage prevailed, and subsequently extended to embrace areas at a distance which may be, rightly or wrongly, correlated with those of England and Western France. The comparisons now drawn are only between the rocks of the original and typical area and of America, excluding the Cretaceous rocks of other countries. Thus restricted, the Neocomian of Europe comprises only shore deposits, characterised by a Cretaceo-Jurassic fauna and a Jurassic flora. The Gault is a deeper sea-deposit, comparable to the "Blue Mud" of the *Challenger*, with a typically Cretaceous fauna and a Jurassic flora. The Upper Greensands are more or less the equivalents of the Gault, deposited under differing physical conditions, corresponding to the "Greensands" of the *Challenger*, and have been assumed to represent the shore or shallower water conditions preceding the Chalk. The Chalk itself is described with a view to prove that it is a truly oceanic deposit, formed at a distance from shore and at a considerable depth, corresponding in all respects with the existing "Globigerina Ooze." The arguments against this view are refuted in detail, and the suggestion made that the alleged shallower habitats in the tropics of the few surviving Mollusca may be due to the lower temperature prevailing now in the abyssal depths of the ocean having driven heat-loving types from the depths at which they were able to live in the Chalk period. The whole Cretaceous series in the British area is the result of a gradual conversion of land into sea, owing to subsidence. The process commenced with the Neocomian, became more serious with the Gault, and continued until the close of the Chalk. The focus of the depression, so far as its results are accessible, was the English Channel, whence it spread in an easterly direction across Central Europe. As the land subsided, the gulf increased in magnitude, and Blue and Green Muds were formed on a wider and wider area, to be succeeded in due time by chalky Ooze. The nearer the focus of subsidence the older the Greensands and Gault, and the farther we recede from it the newer in age they become. The zones of increasing depth travelled outward and forward, and though now represented by continuous bands of the same lithological characters, extending over many countries, it would be rash in the extreme to infer the synchronism of portions of these when separated by degrees of latitude. The time required for these zones to travel from Kent to the Crimea, and to accumulate a mass, mainly composed of minute organisms, of over a thousand feet in thickness, must have been sufficient to account

1 "Economic Geology of India," and "A Geologist's Contribution to the History of India," *Proc. Roy. Dub. Soc.* 1883.

for a very sensible progress in the evolution of organic forms. The deposition of the Chalk commenced in the English area at a period when the land floras were still of Jurassic character. By the time it had reached Limburg, Saxony, and Bohemia, Dicotyledons had become developed. The period required for the chalk ocean to encroach but 300 to 400 miles must thus have been very vast. The question may, however, arise whether plant development at this stage followed the otherwise universal law of evolution, or was exceptionally rapid. The fauna has to be examined to see whether it discloses an equally appreciable progress. The conclusion arrived at is that while the groups with which the author is less acquainted apparently do so, the progress in the Mollusca is unmistakable. The helicoid, turbinate, and patelloid groups are archaic and stationary, but the fusiform shells betray a tendency to elongate their canals, and the relative abundance of such, and gradual dropping out of now extinct genera, furnish an unmistakable index of the relative ages of the more littoral deposits. From this point of view we are able to demonstrate that the Greensands of Aix-la-Chapelle are far younger than their lithological structure and sequence would indicate, while the appearance of such distinctly new developments as cone and cowry shells further support the views of the relatively almost Tertiary, or, at least, transition, age of the Cretaceous series in Denmark. While, therefore, denudation on a truly colossal scale has produced one of the most considerable gaps in the whole geological record between Cretaceous and Tertiary over the British area, beds of intermediate age may successfully be sought for at a distance from this centre. The erroneous correlation of these, bed by bed almost, with the typical Cretaceous series, as developed in England, has led to a still more untrustworthy correlation of the American series with ours. The Cretaceous series of America contains at its very base a flora composed of angiosperms so perfectly differentiated that they are apparently referable to existing genera. One of the oldest floras in Europe containing angiosperms is that of Aix-la-Chapelle, and even this we have seen is relatively modern; but these are not referable in at all an equal degree to existing genera, and even the Coniferæ are embarrassing on account of their highly transitional characters. The oldest Cretaceous flora of America, so far from possessing any Cretaceous characters, agrees in a remarkable manner with that of the English Lower Eocene, while the Laramie, or supposed Cretaceo-Eocene, flora has very much in common with that of our Middle Eocene, and marks a similarly sudden rise in temperature. The question is whether the evidence of the fauna in favour of the Cretaceous age of the series is so conclusive that the floral evidence must be set aside. Taking the Cretaceous series as represented in California, the older stages possess Mollusca of definitely Cretaceous aspect, but those of the newest have a decidedly Eocene facies. To be Cretaceous a fauna must have some elements which did not survive to a later period; but are we in a position to state that the Ammonitidæ, the Belemnites, and Inocerami did not do so? Even our present limited knowledge is entirely opposed to such a view. It must be remembered that the Eocenes in their typical area, England and France, were deposited under peculiar local conditions, and it would be as logical to infer from the absence in them of Cretaceous types that these existed nowhere else as it would be were the bed of the English Channel now upheaved to class as extinct all forms of life not met with in its sands and muds. If, as there is evidence to show, America was isolated at the time, the survival there of forms of Reptilia elsewhere extinct would be in accordance with ordinary observation at the present day. The flora of the American series is Eocene; the fauna of its earlier stages is Cretaceous. We are compelled therefore to choose whether we will believe that a large Eocene flora was developed there during the Cretaceous, or that some members of a Cretaceous fauna lived on to an Eocene date. The former supposition demands greater rapidity of evolution than we are accustomed to admit, and no external evidence is advanced to support it. The latter is more conceivable from the standpoint of evolution, and is not contradicted by any evidence that has yet come under the author's observation.

On Some Remains of Fish from the Upper Silurian Rocks of Pennsylvania, by Prof. E. W. Claypole, B.A., B.Sc. (London), F.G.S., of the Second Geological Survey of Pennsylvania.—The earliest vertebrate animals yet known from any part of the world are some remains of fish in the Upper Silurian rocks of England. They are for the most part of three types. First, short fin-spines, named by Agassiz *Onchus tenuistriatus*; second, fragments of shagreen, or the skin of a placoid fish (*Thelodus* and *Sphagodus*), belonging probably to the same that carried the spine; and third, ovate, finely striated plates or shields, supposed to be the defensive armour of some fish, unlike any now living. No one has doubted the ichthyic nature of the first and second of these three forms. But as regards the third there has been much controversy. Evidently allied to *Cephalaspis*, its right to the name of fish has been called in question, and suspicion has been raised in regard to the whole family of the Cephalaspids. On the whole, however, it seems best to retain them in the class of fishes, and to this conclusion Prof. Huxley evidently inclines in the conclusion of his "Essay on the Classification of the Devonian Fish." One may expect some, or even considerable, divergence of structure from the usual ichthyic types in such early forms. These English fossils occur in the lowest beds of the Devonian (Cornwall), and in the highest beds of the Silurian (Shropshire and Hereford). The well-known Upper Ludlow "bone bed" has yielded them in considerable quantity, and one specimen is reported by Sir C. Lyell in his "Elements of Geology" (1865) as discovered from the Lower Ludlow, beneath the Aymestry limestone. Below this horizon I have never heard of their occurrence. The English Ludlow, taken as a whole, has been usually correlated with the Lower Helderberg of North America, and on good grounds, both containing *Eurypterus* and *Pterygotus*. The English Lower Ludlow and the Water-Lime or basal beds of the North-American Lower Helderberg are the lowest strata containing these fossils. On both sides of the Atlantic they range from this level upwards into the Devonian. The oldest vertebrate fossils yet announced from America are those found in the Corniferous limestone or Lowest Devonian of Ohio. Possibly the beds at Gaspé, on the Gulf of St. Lawrence, are somewhat lower, as they have yielded *Cephalaspis*, which is not yet known from Ohio, and *Coccosteus*, of which Ohio has yielded only a single specimen. No authenticated fish-fossil has yet been announced from the Upper Silurian rocks of America. It is true that reports of the discovery of such remains have been published at various times, but investigation has proved them all erroneous. (See "Palæontology of New York," vol. ii. pp. 319, 320, pl. lxxi.; *American Journal of Science*, second series, vol. i. p. 62; "Palæontology of Ohio," vol. ii. p. 262.) During my recent work on the palæontology of Perry County, Pennsylvania, I came upon some fossils which at once suggested relationship to the Ludlow group above described. Among them were a few spines recalling *Onchus tenuistriatus*, but with some differences. I have named them *Onchus pennyslvanicus*. With them I discovered abundance of specimens bearing a strong resemblance to *Pteraspis*, but larger, and differing in some other respects. These I name *Glyptaspis* (*G. elliptica* and *G. bitruncata*). Comparing these with *Pteraspis* we find them much thinner, not exceeding one-tenth of an inch in thickness; whereas specimens of *Pteraspis* in my possession from Cornwall are nearly one-fourth of an inch thick. The striation on both is equally fine, but is rather less regular on the American specimens. These also show no trace of the spine in which the shield of *Pteraspis* terminates, as shown by Murchison in "Siluria." No traces of the English fossil shagreen—*Thelodus* and *Sphagodus*—have been found in the Pennsylvanian beds, though it abounds in the Ludlow rocks. The fossils were found in a bed of sandstone about 200 feet below the base of the water-lime in Perry County, Pennsylvania, near the top of the great mass of variegated shale composing the Fifth Group of Rogers in the First Survey of Pennsylvania. This shale in New York immediately overlies the Niagara limestone, which is correlated on satisfactory evidence with the Wenlock limestone of England. Ten or twelve species are common to the two beds. It seems, therefore, that the great mass of coloured shale, near the top of which these fossils were found, and which is a continuation of the Onondaga group of New York, has no representative in the British series, but corresponds to an interval between the Upper Wenlock and the Lower Ludlow. (For details regarding the correlation of these beds in Pennsylvania with those in New York, see a paper by the author in *Proc. Amer. Phil. Soc.* for 1884.) It is consequently a necessary inference that the beds yielding *Glyptaspis* and *Onchus* in Pennsylvania are somewhat older than those containing *Pteraspis* and *Onchus* in England. Microscopic examination of the specimens, and a comparison of their structure with that of *Pteraspis* and *Cephalaspis* are in progress, and the details will be given in the paper. Other fossils in the author's possession indicate the possible existence of fish at a still earlier date, but the material is not yet worked out.

On Fluxion-Structure in Till, by Hugh Miller, A.R.S.M., F.G.S., Geological Survey of England and Wales.—It has long been recognised as one of the characteristics of the till that its long-shaped boulders are striated lengthwise. They have, as it has been concisely expressed, been "launched forward end-on." From the minute and magnifiable striæ upon the smaller (*e.g.* almond-sized) boulders it also appears that these at least have been carried forward, involved in the matrix, and were glaciated chiefly by its particles. Under the microscope these particles exhibit most of the varieties of form and glaciation that are found among larger boulders. The structure of the till in open situations shows that the axes of its stones have been turned by a common force in the direction of glaciation; it exhibits a rough structure comparable to the fluxion-structure of igneous rocks, the smaller boulders dividing around and apparently drifting past the larger, like the tide round an anchored skiff. These structures, which have been found by the author over many hundreds of square miles, chiefly in the north of England, indicate that at least a surface-layer of the till was dragged along, with a shearing movement of particle upon particle, producing intimate glaciation within its mass. Proofs are adduced that this moving layer was in general a surface-layer only, and that the till did not, as has often been supposed, move forward *en masse*, licking up its additions from beneath. This is the only intelligible explanation of the order (as well as the structure) of the boulder-clays of which the author has any practical knowledge. In up-lying situations, where the drift consists of raw material, fluxion-structures are seldom detected. In sheltered spots they are not generally developed. They are characteristic of well-kneaded till in open situations, liable, however, to obscuration by contortions within the mass. Of twelve experimental attempts made near the watershed of England in East Cumberland, 600-900 feet above the sea, to determine the ice-movement from this structure alone, eight were correct, three indeterminate, and only one misleading. The pressure and movement capable of producing this widespread fluxion-structure seem to have been that of some mass vast and far-spreading—closely investing, slow-moving, and heavily dragging—such as glacier ice. It needs only to be assumed that the confluent glaciers communicated something of their own movement and structure to the ground-moraine below.

On the Southward Ending of a Great Synclinal in the Taconic Range, by James D. Dana, LL.D.—The Taconic Range, which gave the term "Taconic" to geology, lies in Western New England, between Middlebury, in Vermont, on the north, and Salisbury, in Connecticut, on the south. In former papers, published in the *American Journal of Science*, the author has shown, first, that the rocks constituting the range vary as we go from north to south, from roofing-slate and hydromica (or sericite) schist to true chloritic and garnetiferous mica schists; secondly, that these schists lie mostly in a synclinal or compound synclinal; thirdly, that the crystalline limestone along the eastern foot is one with that along the western, the limestone passing under the schist as a lower member of the synclinal; and fourthly, that since the limestone contains in Vermont (according to the discoveries of the Vermont Geological Survey, and also of Mr. A. Wing), and in the State of New York, fossils of the Lower Silurian, ranging from the inferior divisions to the higher, the Taconic schists are probably of the age of the Hudson River group or Llandeilo flags. The author's papers further show that while a large part of the Taconic Range has eastward dip on both the east and west sides, a southern portion about twelve miles long, consisting of Mount Washington in south-western Massachusetts and its continuation into Salisbury, Connecticut, is a broad tray-shaped synclinal, the dips of the two sides being toward one another, like the sides of an ordinary trough. The width of the broad synclinal between the limestone belt on either side is about five miles. As the result of investigation during the last two years, the synclinal character of this Mount Washington part of the Taconic Range is illustrated in the paper by new sections, and by facts connected with the dying out of the great synclinal (or compound synclinal) in the town of Salisbury. The mean height of Mount Washington above the sea-level is about 2000 feet, and above the wide limestone region on either side and to the south, about 1250 feet. The synclinal virtually ends along an east and west line through the village of Lakeville, in the town of Salisbury, where a beautiful lake lies within the limestone area. The surface of the mountain region descends 1000 feet in the southern, or last, three miles; and in the latitude of Lakeville, the width, as the map presented shows, diminishes abruptly from five miles to a narow neck of six-tenths of a mile. The area south is of limestone, and the neck of schists referred to is hardly 150 feet in height above it. The limestone may in some places be seen emerging from beneath the schist at a small angle; and at one locality a low oven-shaped anticlinal of limestone has the schist covering all but a narrow portion at top; the quarrymen had to remove the schist to work at the limestone. Several narrow strips or belts of limestone, S. 15° W. in direction, corresponding with the direction of this part of the range, show out through the sides of the mountain where local anticlinals have had their tops worn off. Further, the dip of the schist over much of the southern slope is southerly and at a small angle, but with many local anticlinals and synclinals. In addition, there are small areas of schist *in the limestone* region, like straggling portions of the dwindled mountain, which appear in general to be remains of local flexures. There is the plainest evidence that the limestone formation of southern and south-eastern Salisbury comes out from beneath the dwindled, flattened-out, and worn-off mountain synclinal. And the reason why this limestone is exposed to view over plains miles in width, east and west of the Taconic Mountain, as well as to the south, is simply this, that the once overlying schist has been removed because in badly broken anticlinals and synclinals. The paper closes with an allusion to the orographic, stratigraphical, and lithological interest of the facts, and to their important bearing on the question of the origin and chronology of certain kinds of crystalline rocks, such as chloritic, garnetiferous, and staurolitic mica schists, as well as others less coarsely crystalline.

The Primitive Conocoryphean, by G. F. Matthew, A.M., F.R.S.C.—Relates to the development of the species *Ctenocephalus matthewi* and other Conocorypheans of the Acadian fauna, and is considered under the three heads, viz., the Development of the Glabella; the Acquisition of Sensory Organs; and the Decoration of the Test. Under the first head it is shown that the peculiar glabella of the species above referred to is closely related to the early history of the trilobite. The glabella, in its earliest stage, is very different from that of the adult, and in outline is not unlike that of *Paradoxides*; it also resembles this species in the position of the ocular fillet. At the next stage the glabella or axial lobe becomes trumpet-shaped, as in *Carausia*, and in the third the glabella proper is developed by the segmentation of the axial lobe: the glabella and ocular fillets now resemble those of *Ptychopar a*. In the following stages the family characters of the Conocorypheans begin to assert themselves, especially the widening of the base of the glabella, the appearance of the canals connected with the ocular ridges, and the development of spines. (2) *The Acquirement of Organs of Sense.*—The ocular fillet appears, in the second stage of growth, as a faint, narrow ridge, close to the anterior marginal fold, and extending but a short distance from the glabella. It is not until the fifth stage of growth that the ramifying branches which spread from the ocular ridge to the anterior margin made their appearance. The ocular lobe and sensory apparatus connected with it are more distinctly visible on the under than on the outer surface of the test, and the canalets connected with the lobe spread over the anterior slopes of the shield, and extend to the anterior margin. In the tuberculated species they connect by hollow spines with the outer surface. In one species they cover a wider space than in the others, extending some distance behind the ocular ridges and over the front of the glabella. (3) *Decoration of the Test.*—In all the Acadian species of this group but one, the surface of the test at maturity is covered with tubercles and spines similar to the surface-markings of *Conocoryphe sulzeri*, &c. In the earliest stages, however, no such tubercles are found, but the surface appears smooth or scabrous. In *Ctenocephalus matthewi* the surface, in the first three stages of growth, appears smooth; in the fourth, tubercles begin to appear, and about the fifth stage all projecting parts of the test are studded with them. Those on the glabella and frontal lobe are arranged in transverse rows, those on the cheeks in interrupted rows conforming more or less to the periphery of these protuberances. Towards the adult stage these tubercles and spines become more irregular in position and number, conforming in this respect to the law of development in the Ammonites, expounded by Prof. Alphonso Hyatt.

The Value of Detailed Geological Maps in relation to Water-Supply and other Practical Questions, by W. Whitaker, B.A., F.G.S., Geological Survey of England.—Those maps of the Geological Survey of England in which various divisions of the

Drift have been coloured tell us, as a rule, a very different tale from the corresponding sheets in which the Drift is ignored, and it is only these Drift maps that really give us a true idea of the nature of the surface. Indeed in many districts a geological map that does not show the Drift is comparatively useless for most practical purposes, at all events in a populous country like England. Moreover, it is not merely enough to mass Drift as such, but its constituent members should be fairly distinguished, not merely with regard to their classification or relative age, but also as to their composition, whether of clay, loam, or gravel and sand. To illustrate this there are exhibited copies of the two versions of many of the Geological Survey maps of the London Basin, with and without Drift, from which the following important points will be at once seen:—(1) Large tracts, shown as Chalk on one version, really consist, at the surface, of the generally impervious Boulder Clay, whilst over others the Chalk is covered by Brick-earth and Clay-with flints: all these beds being such as give an aspect to the country very different to what we find where the Chalk is bare. (2) Parts of the wide-spreading area of the London Clay (of the Driftless maps) are really quite altered and deprived of their clayey character, by the sheets, long strips, and more isolated patches of gravel and sand that occur so often, whether along the river-valleys or over the higher plains. (3) The sandy, permeable Crags are in great part hidden by Drift, which, though often consisting of sand and gravel, is sometimes of Boulder Clay. Indeed, so widespread is the Glacial Drift in the greater part of Norfolk and Suffolk, that only a Drift edition of the Geological Survey maps of the eastern parts of those counties has been issued; a map without Drift would necessarily be a work of fiction. To illustrate the important bearing which these Drift maps have on a great question, that of water-supply from the Chalk, the author also exhibits some special maps, which he has made to show the areas over which rain-water has access to the Chalk, as distinguished from those over which the surface-water cannot sink down into the Chalk, or can only do so very partially. These maps will be more particularly noticed in Section G.

Pennsylvania before and after the Elevation of the Appalachian Mountains, by Prof. E. W. Claypole, B.A., B.Sc., F.G.S. Lond.—The paper, of which the following notes are an abstract, is intended as an attempt to handle, in a necessarily imperfect manner, and only to first approximations, a difficult but important and interesting geological subject. The method of treatment is, in the writer's opinion, one that has not hitherto been employed for the same purpose. The object in view is to form some estimate, as near to the truth as possible, of the amount of compression or shortening produced at the surface by the corrugation of the upper layers of the coast into mountain chains, with especial reference to the American Atlantic seaboard. In order to confine the paper within due limits, certain propositions must be taken as proved. The principal of these are:—(1) That central contraction has developed tangential pressure in the crust; (2) that the tangential pressure has produced crumpling of the crust; (3) that to this crumpling are due long ranges of mountains; (4) that the Appalachian Mountains came into being in this manner in the later portion of the Palæozoic era. These admitted, the conclusion necessarily follows that during the formation of the Appalachian Mountains a considerable contraction of the crumpled area ensued, in a direction at right angles to that of the chain. The following points constitute the main features of the paper:—(1) Short account of the great ranges of Pennsylvania, in plan and section, with diagrams; (2) situation and account of the line of section adopted; (3) limitation of the field to a consideration of eleven great ranges—Blue Mountains, Bower Mountains, Conecocheague Mountains, Tuscarora Mountains, W. Shade Mountains, Black Log Mountains, Blue Ridge Mountains, Jack's Mountain, Standing Stone Mountains, Tussey Mountains, Bald Eagle Mountains; (4) Discussion of the different parts of this section—(*a*) the Mountain Region, (*b*) the Cumberland Valley; (5) attempt to estimate or measure the curved line of the crumpled Upper Silurian (Medina) sandstone; (6) inference that the sixty-five miles of the line of section represents about 100 miles of surface previously to the crumpling of the crust and elevation of the mountains; (7) this result, for several reasons, below rather than above the truth; (8) geographical effects of this contraction; (9) development of the fact that such elevation of mountains by tangential pressure involves not only elevation, but considerable horizontal movement; (10) diminution of motion to north-west; (11) a few words on the failure of attempts yet made to account for this contraction; (12) suggestions and conclusions.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

At King's College Prof. W. Grylls Adams, F.R.S., will deliver a course of lectures on Electricity and Magnetism and their applications to Electric Lighting, Transmission of Power, &c., during the academical year 1884-5. A course of practical work in electrical testing and measurement, with especial reference to electrical engineering will also be carried on under his direction in the Wheatstone Laboratory. The lectures will be given once a week—on Mondays at 2 p.m.—and the Laboratory will be open on Wednesdays and Fridays from 1 to 4.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, September 15.—M. Rolland, President, in the chair.—Address delivered at the inauguration of the Fresnel Monument at Broglie, by M. Jamin.—Remarks on algebraic equations, in connection with a communication from M. de Jonquières on the application of geometry to algebra, by M. Léon Lalanne.—Note on the two methods, proposed by Hamilton and Sylvester, for resolving the linear equation in quaternions, by Prof. Sylvester.—On the composition and properties of the light emitted by insects of the Pyrophore genus, by MM. Aubert and Raph. Dubois. Examined under the spectroscope, the spectrum of this light appeared very beautiful, continuous, and destitute alike of very bright and dark bands. It occupied about seventy-five divisions of the micrometer, extending on the red side to the centre of the interval separating the A and B rays of the solar spectrum, and on the side of the blue a little beyond the F ray. When its intensity diminishes, the red and orange disappear altogether, the spectrum being then reduced to the green with a little yellow and red, the green persisting longest. The reverse takes place when the insect begins to glow. Thus the least refrangible rays are the last to be emitted, a result hitherto observed in the spectrum of no other luminous body, except to a limited extent in that of the sulphide of strontium. Examined to ascertain its photo-chemical properties, this light showed a feeble display of the phosphorescence of the sulphide of calcium.—Remarks on a singular case of deformation in the images observed through telescopes, by M. Govi.

Berlin

Physiological Society, August 1.—Dr. A. Auerbach had made experiments to ascertain which of the constituents of flesh exercised the acid, alkali-abstracting effect on the blood witnessed in the reaction of the urine of flesh-eating animals compared with that of the urine of plant-eating animals. He found that the acid phosphoric potash increased the ammoniacal contents of the urine in a manner similar to that of the administration of acids. A dog fed on flesh having been brought into nitrogenous equilibrium, and kept in this state for some days, had a portion of acid phosphoric potash given to it in addition to the meat. The nitrogenous excretion remained the same as before, but the quantity of secreted ammonia had considerably increased, and this increase continued for some days after the dog was put back to the former flesh diet without the salt. The quantity of secreted ammonia corresponded, to the utmost nicety, with the quantity necessary for the conversion of the salts which had been taken, PO_4KHH, into PO_4KNO_4H.—Prof. Kronecker gave a report of a series of experiments conducted during the session now ended in the department of the Physiological Institute under his care. He first recounted the experiments of Mrs. Dr. Boll, who investigated whether asphyxiated fishes could recover animation without a supply of oxygen, and simply by withdrawing the carbonic acid from them. Goldfishes were left in boiled water free of air till the symptoms of asphyxia became distinctly manifest, and then a somewhat diluted caustic lye was added to the water without the admission of air. In every such case the fishes soon recovered their lively movements, and swam about freely in the water. It might therefore be concluded that, with the discharge of the surplus of carbonic acid, the symptoms of asphyxia would also disappear.—Prof. Kronecker then reported on the experiments of Dr. Kranzfeld, which had for their subject the movements of the stomach. In the stomach of each of the animals examined, the cardiac part, the pyloric part, and the middle had to be discriminated. Of these three parts the last was in most cases immovable, while the two other parts displayed lively movements. In the act of

swallowing, as observation proved, the stomach took no share. The cardiac and the pyloric parts were excitable in different manners. The pylorus reacted strongly even on slow electric stimulations of moderate intensity such as failed to induce any contraction in the cardiac part. Contraction of the cardiac part followed however more frequent stimulations. The act of vomiting, at least in all the animals examined, was constantly brought about by a swallowing movement. In the discharge of the contents of the stomach, on the other hand, the œsophagus took no part whatever. The motors at work were the abdominal pressure and the movements of the gastric walls, and during the time the vomiting lasted the cardiac orifice was open. The whole mechanism of the act of vomiting was still, however, the subject of investigation. —Dr. Jastreboff has made a particular investigation of the question, important in practice, regarding the effect on the blood-pressure of interference with different parts in the case of operations in the peritoneal cavity. He found that the blood-pressure was raised by all encroachments of this kind, especially that of impinging on the intestine, and, most strongly of all, by a refrigeration of the intestine. In the case of a quick excision of a warm tumour from the peritoneal cavity the blood-pressure rose to quite a rapid rate, and the influence of ether was only able somewhat to abate it.—In continuation of former experiments on the movements of the vagina, Prof. Kronecker has further established that they are not peristaltic movements like those of the intestine, but that the vagina contracts, exactly in the same manner as does the œsophagus, in sections which in definite numbers (mostly three) and in definite series compress themselves from the top downwards. A solution of continuity in the wall of the organ in no respect affected the course of the contraction.—Dr. Ratimoff has studied the effect of chloroform on the heart and the respiration. In order to charge the air with the vapour of chloroform a special apparatus was constructed which allowed an exact registration of the chloroform. Air completely saturated with chloroform contained in every case, whether the process of interfusion took place slowly or rapidly, 30 cubic centimetres of chloroform to 100 litres of air, and invariably caused the death of the rabbits subjected to it, and that through paralysis of the heart. Such a mixture as produced a complete narcosis of the animal, without affecting the heart or the respiration, contained 5·6 or 7 cubic centimetres of chloroform to 100 litres of air, a mixture which was able to maintain the narcosis for hours at a time. In these experiments, however, it appeared that the animals very soon got accustomed to the chloroform, and if, for example, the narcosis was effected at the beginning by a proportion of 5 cubic centimetres of chloroform, the dose had subsequently to be increased to 6 and 6½ cubic centimetres in order to keep up the narcosis.—Dr. Schapiro has investigated the effect of atropine on the frog's heart, and has found it analogous to the effect of heat. The heart became through its application much more accessible to external treatment than in a normal state, and in general its effect may be formulated in the statement that by means of atropine the fissures in the frog's heart become widened. —Mr. Aronsohn had formerly found that 0·73 per cent. solution of ordinary salt was of altogether indifferent and unstimulating effect on the nasal mucous membrane, and offered the best vehicle for the introduction of smelling substances. He now communicated that he had examined other salts, in particular carbonate of soda, sulphate of soda, sulphate of magnesia, &c., with a view to determining in what concentration they affected the nasal mucous membrane with equal indifference as did 0·73 common salt solution. He found that for this purpose much more considerable quantities of these salts were required. In the case of sulphate of soda, for example, four times the quantity that sufficed in the case of common salt was needed to produce the same absence of effect. In such stronger concentrations these solutions might take the place, either in whole or in part, of the kitchen salt solution.—Dr. Heimann reported on a new method for the production of localised pressure on the cerebrum. He placed an animal at the periphery of a round chest made to revolve round its centre, caused it to rotate 300 times a minute, and observed paralytic symptoms which passed away in a short time after the end of the rotation. By experiments he convinced himself that the change in the distribution of the blood in the two halves of the brain produced by the centrifugal force was without influence in this phenomenon, and therefore concluded that it was exclusively the one-sided pressure of the brain against the skull which caused the paralysis. To still further localise this pressure he trepanned the skull at a spot where it was known that the part of the membrane of the cerebrum there situated was the centre for the movements of an extremity, fixed into the opening a cork stopper, which of itself exercised no pressure, and placed the animal in such a posture in the rotating apparatus that the operated side was situated outwardly. In the rotation the spot in question was now pressed against the cork, and so paralysis showed itself in the extremity appertaining to that spot. On the cessation of the revolution the movement of the paralysed part was soon restored. These experiments could be repeated at pleasure without doing any harm to the animal.

Vienna

Imperial Academy of Sciences, July 17.—K. Laker, on the first microscopic phenomena of coagulation of mammalian blood.—A. Weiss, on a peculiar occurrence of calcium oxalates in the epidermis of the organs of some Acanthaceæ.—On spontaneous movements of vegetable dyeing bodies, by the same.—Preliminary note on a peculiar solved yellow dye in the flowers of some Papaveraceæ, by the same.—L. Boltzmann, on the properties of monocyclic systems and of other systems allied with them.—H. List, on the epithelium of the cloaca of *Scyllium canicula*.—K. Zulkowsky and K. THE "CHALLENGER" REPORTS

ort of the Scientific Results of the Voyage of H.M.S. Ch illenger" during the Years 1873-76 *under the ommand of Capt. George S. Nares, R.N., F.R.S., and apt. Frank Tourle Thomson, R.N.* Prepared under e Superintendence of the late Sir C. Wyville Thomson, nt, F.R.S., &c., and now of John Murray, F.R.S.E., ie of the Naturalists of the Expedition. Zoology—ol. IX. Text and Plates. Two Vols. (Published by rder of Her Majesty's Government, 1884.)

NOTHER volume forming Part XXII. of the Zoological Series of Reports on the Scientific Results of the *'llenger* Expedition has just been published, containing ıccount of the Foraminifera by H. B. Brady, F.R.S. ill be universally acknowledged that the task of preıg this Report could not have been intrusted to abler ls. The representatives of this interesting group of ıals, writes Mr. Murray in an editorial note, are ersally distributed over the floor of the ocean and in urface and sub-surface waters, and the presence or nce of certain surface forms in the deposits from difıt depths and localities is intimately connected with of the most remarkable and intricate problems of ral Oceanography. It was therefore of the first ortance that one very familiar with the group of the minifera should have been chosen to undertake so an amount of labour as was requisite to investigate enormous quantity of material that was collected. Report itself is the best evidence of the great success h has attended Mr. Brady's investigations; it conof a volume of text of over 800 pages, and is accomed by a volume of 115 very exquisitely executed s.

hile the chief part of the Report is taken up with the riptions of the new or rare species of Foraminifera shed by the various bottom-dredgings and tow-net erings obtained during the *Challenger* Expedition, author has also included some account of the colons made in the regions of the North Atlantic, which, gh not visited by the *Challenger*, were explored ıg the expedition of the *Porcupine* in 1869, and he nade the survey of the group more complete by also ring to the forms found during the cruise of the *ght Errant* in 1880, and during the British and ro-Hungarian North Polar Expeditions.

ıe Report, however, contains a great deal more than riptions of new or rare species. From Mr. Brady's acquaintance with the multifarious forms to be met in the group and with its literature, he has been led to treat in a full and able manner the subject of classification of these forms, and has thereby deve1 this Report into an elaborate monograph of recent minifera.

an admirably written introduction a sketch is given ıe gradual development of our knowledge of these s from the time of D'Orbigny (1826) to the present, an elaborately compiled bibliography is appended. various classifications of the Rhizopods, from that of Dujardin in 1841 to that of Leidy in 1879, are glanced at. More details are given as to the various attempts at classifying the Foraminifera, and the author proposes a scheme differing in many respects, and often widely, from those given by previous writers, but one which, in its essential elements, is in no way incompatible with the different conclusions at which they had arrived. The nature of the investment of the animal—that is to say, the minute structure of its test—as an exclusive basis for the primary divisions of the order, has been abandoned. While under all circumstances it furnishes important characters, and is even in some families quite distinctive, it is nevertheless a fact that, whilst there are certain groups which are invariably arenaceous, and some which are always calcareous and perforate, there are yet others in which no uniform rule obtains. The author omits any division of the order into sub-orders, not finding any easily-recognised characters to serve as a basis for such subdivision, and he divides the order at once into families. These families are (1) Gromidæ, (2) Miliolidæ, (3) Astrorhizidæ, (4) Lituolidæ, (5) Textularidæ, (6) Cheilostomidæ, (7) Lagenidæ, (8) Globigerinidæ, (9) Rotalidæ, (10) Nummulinidæ. The Gromidæ, a family composed chiefly of fresh-water organisms, "have been a source of considerable trouble, on account of the want of accuracy and detail in the published descriptions of a number of types more or less closely allied to the group, and only such genera have been included as are known to have long, reticulated pseudopodia." In this portion of the subject the author has had the advantage of the advice of his friend William Archer. "The sub-family Dactyloporinæ, which in the original draft was placed with some reservation amongst the Miliolidæ, pending the fuller publication of the results of Munier-Chalmas's researches, is now entirely omitted. The examination of specimens brought under my notice by E. Perceval Wright and C. Schlumberger has removed any doubt left on my mind as to the propriety of the transfer of the entire group to the calcareous Algæ." The singular genus Bathysiphon of Sars has been removed to the Astrorhizidæ.

With reference to the subject of nomenclature, the following are Mr. Brady's views, which seem founded on common sense, and with which we entirely agree. It is surely not requisite in a group like this "that a uniform standard of fixity of characters should be adopted, or that a set of beings of low organisation and extreme variability should be subjected to precisely the same treatment as the higher divisions of the animal kingdom. The advantages of a binomial system of nomenclature have not diminished since the days of Linnæus, though the views of the naturalist as to what constitutes a 'genus' or a 'species' have changed, and will probably continue to change, but, be that as it may, the Linnæan method is too simple and convenient to be abandoned without some better reason than the different value of these terms as employed in different zoological groups." "The practical point upon which all are agreed is that it is impossible to deal satisfactorily with the multiform varieties of Foraminifera without a much freer use of distinctive names than is needful or indeed permissible amongst animals endowed with more stable characters." All who have had any experience of the life-history of these Rhizopods, who know their immense plasticness, and yet

who remember their, within certain limits of deviation, fixedness of type, will cordially agree with this.

The subject of dimorphism is alluded to, and the two quite distinct phenomena among Foraminifera described by this term are explained, but the author does not seem to select one of these above the other for the exclusive right to the term, as would seem desirable.

One of the most interesting subjects in reference to deep-sea deposits is their direct connection with the pelagic species of Foraminifera. As a rule these forms are not of pelagic habit; on the contrary, probably 98 or 99 per cent. of the known species or varieties live in the sand or mud of the sea-bottom, and possess no powers of floating or swimming; but, on the other hand, some few forms, belonging to eight or nine genera, do most certainly pass their existence either in part or in whole at the surface of the ocean, or floating at some depth below that surface. These forms are found, too, in immense profusion, and a relatively very large mass of the oceanic deposits consist of their calcareous shells. A list of the at present ascertained pelagic forms is given. The most prominent genera are Globigerina, Pulvinulina, Hastigerina, Pullenia. The question seems still unsettled as to whether the species are exclusively pelagic, passing the whole of their time living at or near the surface, or whether they can or do pass a certain portion of it on the sea-bottom. Mr. Brady adduces a series of facts which tend to the inference that the Foraminifera which are found living in the open ocean have also the power of supporting life on the surface of the bottom-ooze, and further, so far as our present knowledge goes, there is at least one variety of the genus Globigerina which lives only at the sea-bottom; but the author is most cautious not to express any dogmatic opinion on the subject.

In dealing with the composition of the test, the presence of a considerable percentage (6 to 10) of silica has been established as existing in the arenaceous forms. The substance secreted for the incorporation of the foreign bodies which cover the test has been proved to be composed of ferric oxide and carbonate of lime in variable proportions, the former being often in considerable excess. It is not without interest to note the presence in some of the porcellanous forms of a thin siliceous investment. A few Miliolæ from soundings of a depth of about four and a half miles, with somewhat inflated segments, scarcely distinguishable in form from young thin-shelled specimens of a common littoral species, were found to be unaffected by treatment with acids, and upon further examination it became apparent that the normal calcareous shell had given place to a delicate homogeneous siliceous investment. While immersed in fluid, the shell-wall had the appearance of a nearly transparent film, and this when dried was at first somewhat iridescent.

A list is given of those stations from which soundings or dredgings were obtained in sufficient quantity to furnish good representative series of Rhizopods, and maps are appended showing the tracks of the *Challenger*, with these stations marked, as also of the areas explored by the *Porcupine* and the other northern expeditions.

Any generalised summary of the details of the new forms would be impossible. Of the several hundred species described and figured, over eighty are here noted for the first time, and this without counting numerous well-marked and named varieties, or the numerous new forms already diagnosed in Mr. Brady's preliminary Reports.

The family Astrorhizidæ is the one which has received the largest number of additions; indeed our acquaintance with the larger arenaceous Rhizopods is almost entirely derived from the various recent deep-sea explorations. A knowledge of the life-history of these forms is still needed to place the classification of the group on a secure basis, and as some few of the forms are inhabitants of comparatively shallow water, their investigation would seem to be well worthy of the attention of observers at some of our zoological marine stations. Many other problems to be solved are also pointed out in this Report, the extreme value of which will be recognised by all students of biology.

THE ENGLISH FLOWER GARDEN

The English Flower Garden: Style, Position, and Arrangement. Followed by a Description, Alphabetically Arranged, of all the Plants best suited for its Embellishment; their Culture, and Positions suited for each. By W. Robinson, with the co-operation of many of the best Flower Gardeners of the day. Illustrated with many Engravings. (London: John Murray, 1883.)

A LOVE of flowers seems more or less characteristic of most human beings, and the tending and caring them is to most people a pleasant labour. Their brightness of colour, their charm of form, the sweetness and refreshingness of their varied perfumes please and delight the senses, while the mystery of their lives and deaths captivates the mind and awakes up the pleasures of hope. In no European country has this love of flowers been more manifested than in England, so that a flower garden seems an indispensable adjunct of an English home. It too often happens that many of those who love flowers have not the knowledge requisite to take care of them, and then the flower garden is handed over to the care of others. What to grow and what not to grow becomes then not so much a question of deliberate enlightened forethought as a thing of fashion, commonplace and unstable. No honest lover of Nature, no one who has once known the beauties of plant life, could ever for a moment remain pleased or satisfied with the arrangement of things out of place which is so peculiarly characteristic of one style of modern English gardening. It was not always thus: anywhere in Continental Europe that one visits "Le Jardin anglais" of some fine demesne or of some public park, there one is sure to find some attempt to form a natural prospect by the judicious arrangement of tree, shrub, flower, and grass; but in England itself, the very home of Sylvia, all traces of Nature are too often obliterated, and a meretricious display of colour, inclosed within a sharply defined geometrical sameness of outline, takes the place of a refreshing contrast in contour accompanied with joyful surprises of brightness. What a difference there is in the pleasure of viewing a large mass of *Gentiana acaulis* in the centre of a wide expanse of scarlet geraniums encircled with yellow calceolarias and viewing some few tufts of the same plant opening their blue corollas amid the grass by the borders of some Alpine meadow. Those who love gardens and like to see in them some few touches

Nature owe a debt of gratitude to Mr. W. Robinson for life-long labours in disturbing our minds as to the rrectness of modern views on gardening, and for in a eat measure destroying the miserable conventionality at had made our gardens bad imitations of very inistic carpets, or of nightmare-giving wall-papers. But destroying what was bad it was also most desirable to ild up something good to replace what was gone, and the present most welcome volume we find indications, ear and distinct, of the abounding wealth of flowers at r disposal which are fitted for the embellishment of our en-air gardens. In the compilation of this work on e "English Flower Garden," Mr. Robinson has had the -operation of some of the most practical and thoughtful iters of the day, and also the valuable aid of Mr. W. oldring, whose experience as superintendent for some ne of the Hardy Plant Department of the Royal rdens at Kew has well qualified him for the task. The st part of the work—On Gardens, their Arrangement, —is for the greater part from the pen of the author. e should have liked that a small portion of this part had en devoted to the subject of town and suburban gardens small size. Many a modest cottage garden has, we read, lessons to give, but then our ideas of a modest cottage rden are not helped by an illustration of the charming ounds attached to Sheen Lodge. The second part ntains in alphabetical order a list of the more important nera and species of plants which will grow in the open r in Great Britain or Ireland, with figures, some very od, some indifferent, of most of the more attractive ecies. In some few cases we notice figures given which e not referred to in the text; when these are not of lesirable" species for the flower garden, as in the case *Gentiana lutea* and *Scilla maritima*, it would have been tter to have put others in their place. To all our aders who have or contemplate having a garden we rdially recommend this very excellent book.

OUR BOOK SHELF

he King Country: or Explorations in New Zealand. By J. Kerry-Nicholls. (London: Sampson Low and Co., 1884.)

his interesting volume Mr. Nicholls describes a good ce of exploring work. The King Country, with which volume is largely concerned, is that district of the th Island of New Zealand which is still under the y—not entirely nominal—of the King Tawhiao, who only recently left our shores. It occupies a very large . between the west coast and the Lake Taupo region, ng on its north-eastern border that wonderland with ch the late Baron Hochstetter has made us familiar. additional details of the sub-volcanic action of this on, its boiling springs and glistering terraces, are ome. From Rotomahana Mr. Nicholls travelled hwards in a zigzag to Lake Taupo, and geologists be specially interested in the observations reling the great volcanic plateau on the south of e Taupo, and Mr. Nicholls's account of his ascent Mounts Tongariro and Ruapehu, the former still a state of volcanic activity. In fact there is unding evidence that at no very remote period volc action must have been widespread and copious a very large area of the North Island. Though not e compared with the Southern Alps, which Mr. Green his companions scaled last year, still Mr. Nicholls's was formidable and trying enough. In the King Country the natives have retained many of their original characteristics and customs almost unchanged, and therefore such narratives as that of Mr. Nicholls is of considerable value to the ethnologist. The region is richly wooded, the scenery in many places magnificent, and the geological features well worth minute investigation. In an appendix we find a list of the New Zealand tribes with their localities, and careful lists of the flora and fauna met with during Mr. Nicholls's journey. Altogether the narrative is interesting, and contains a good deal of fresh information. There is an excellent map and many attractive illustrations.

Forests and Forestry of Northern Russia and Lands beyond. Compiled by John Croumbie Brown, LL.D. (Edinburgh: Oliver and Boyd, 1884.)

THE forestry of Russia has so recently been the subject of an article in our columns, that we need do little more than refer to this, the latest of the long series of volumes by Dr. Brown on his favourite *Forstwissenschaft* or forest science. It appears to have been compiled *apropos* of the International Exhibition of forest products in Edinburgh, and is intended "to introduce into English forestal literature detailed information on some of the points on which information is supplied to students at the schools of forestry on the Continent." The information contained in the volume has been obtained personally during journeys in Russia, or from the best official sources. There is also, it should be said, much to interest the most general and careless of readers, for Dr. Brown quotes extensively from the best recent writers on the districts of Russia to which his book specially refers.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

M. Thollon's Views of "Great B" in the Solar Spectrum

THE excellence and power of M. Thollon's prisms have become proverbial in the spectroscopic world. For the sake, therefore, of having his own account of what he has himself seen (NATURE, vol. xxx. p. 520), with physical apparatus of gigantic size, so well planned, so admirably constructed, and manipulated with such matchless skill,—doubtless every reader will make very little objection to any small accompanying inaccuracy in one outside reference.

To me, therefore, as well as probably to every one else, it is a very trifling matter that he should lay to my charge that I have said "Great B" does *not* increase in intensity as the sun approaches the horizon; although in my "Madeira Spectroscopic" book I have actually introduced Plate 5 to show, as compared with Plate 4, that it does so increase very notably.

But the real point of interest, of special importance just now, and perplexity too, is not that there is *some* effect of the telluric character in the "B" lines—but how much? and in what manner does it grow with zenith distance?

Now that residual question does not seem yet to have occupied M. Thollon, or he would have described the different rates at which the dry gas lines of "B" grow with zenith distance compared with the lines of watery vapour; and, as a first and easy result, he would undoubtedly have obtained, as I have with far inferior means, an indication that the water-vapour of the earth's atmosphere is confined to the lower strata only, while the dry gas composing "B" belongs more nearly to the whole atmosphere, high and low. To that too, at least; for some observations of "B" when near the zenith, or looked at through the shortest aërial path possible at the place, showed me so immense an intensity still in its lines, as to lead to the suspicion

that *part* of their producing gas may be even far outside the usually considered limits of everything belonging to the earth.

M. Thollon, indeed, gives a view of the "B" region, "as," he says, "it would appear if observed outside the earth's atmosphere"; and therein he shows every line constituting our magnificent earthly constellation "Great B," absolutely wiped out of existence—a few *ultra*-faint, accidentally intruding solar metallic lines alone excepted. But how has the eminent *savant* obtained that view? Not by ascending in a balloon, or up the sides of a high mountain above all the grosser atmosphere, and seeing that it was so, but merely by observing some small amount of difference of effect, at two slightly different degrees of large zenith distance, viz. 60° and 80°, at the Observatory of Nice.

Two points, however, alone, will never enable a curve to be drawn on their sole authority; and as a curve of effect is what the investigation now requires, M. Thollon's hitherto merely duplex observations will acquire a far greater power of conviction for other men's minds, if he will kindly supplement them with others at 20° Z.D., or as near to it as the latitude of Nice will allow him at time of summer solstice. Still more would he make us all his debtors if he would repeat those three angular directions at three successive stations at greater hypsometric altitudes; duly remembering that while every one knows that water-vapour and oxygen (the gaseous parentage of "B" according to the grand experiments of M. Egoroff) do exist in the earth's atmosphere, that does not, by itself, therefore render them impossible in greater or less quantity to the outer region of the sun's envelopes; or, in a highly attenuated degree, to the 92,000,000 of miles of space between. C. PIAZZI-SMYTH

15, Royal Terrace, Edinburgh, September 27

Shifting of the Earth's Axis

WITH reference to the letter of Mr. W. M. Flinders Petrie (NATURE, September 25, p. 512), I would remark that there has been no sensible change in the latitude of Greenwich (as found by observations of circumpolar stars) during the last forty-seven years, a period nearly twice as long as that covered by the Pulkowa observations which M. Nyrén has discussed. In a paper on the "Systematic Errors of the Greenwich North Polar Distances" (*Mem. R.A.S.* vol. xlv.), I have exhibited the results for the co-latitude of the centre of the Greenwich transit-circle for each year and for groups of years from 1836 to 1877 reduced to the same refractions throughout (Bessel's), and corrected where necessary for index-error of the thermometer, and the accordance of the individual results is as close as can be expected, when allowance is made for the systematic errors to which all observations are liable, but which are usually ignored in estimating theoretically the probable errors of mean results. It may suffice if I here give the results for co-latitude for three periods of years:—

1836-49	mean co-latitude 38° 31′	21″·85
1851-65		21″·87
1866-83		21″·85

The first and last results are identical and are absolutely inconsistent with Mr. Petrie's supposed increase of the Greenwich co-latitude of 1″ or more in a century.

Royal Observatory, Greenwich, S.E., September 27

The Sky-Glows

FROM the great purity of the sky this evening, and from the flatness of the horizon westwards, on the line of the Great Northern Railway between Huntingdon and Hitchin, the sunset glow was of a very beautiful description. At five minutes before six (watch-time, three or four minutes slow) the sun set; and it was no sooner hidden than a parhelion-like patch of white light, 6° or 8° in diameter, brighter than the rest of the sky, occupied a place 10° or 15° above the sunset point of the horizon, and continued shining there with pearly brightness for about ten minutes. The horizon-line became edged at the same time with bright red, melting abruptly away upwards into orange, and higher up into a field of yellow light round the lucid spot. At 6.5 this spot's white light began to acquire a rosy tinge, and during the next ten minutes, until 6.15, it became intensely rose-coloured, preserving its definite place unchanged in the upper expanse of yellow; a vivid golden oriole-yellow stripe some degrees broad divided it from the red fringe along the horizon, the dazzling gold colour shading exquisitely into the fiery red below and rosy red above, and deriving itself from the latte bronze-like greenish cast in its bright golden hue by contrast.

By 6.15 the rosiness of the bright spot had extended upw and outwards from its centre, and was now blended in its col and confines with the yellow band and red fringe below it, u the whole presented a conflagration or red aurora-like outb of light in the west, 20° or 25° high, and extending 45° or 50 base along the horizon.

The yellow belt was fading out of this glory, and the bri ness and rosiness of its upper part was fast disappearing, w at 6.15 there appeared, with extreme quickness in the brig base, dark intervals dividing it into upward radiating diverg beams of light, which rapidly acquired such fixed breadths distinctness that I easily counted six or eight separate be nearly equidistant from each other, and of equal lengths strengths, marking out plainly by their divergence the s place, and the considerable depth to which it had already s below the horizon. The two outer ones only of the beams, the northern side, were a little confused together, and ma the symmetry which the whole presented, but the full num of their display was several times counted over during the minutes—until 6.25—that they continued visible. They w about 15° long from their bases, and extended across and usur to themselves the light of what had been the golden-yellow b but they gradually shortened and became dull red when at latter hour the horizon assumed the red appearance whic usually presents some time after sunset. The above stri phases of the glow,—the white spot, the rose-red one, and streamers,—occupied just ten minutes each, and the unu aspect of the sky ceased entirely just thirty minutes after sun

The patch of whitish light observed this evening had all appearance of a true, but extended and diffused, mock sun some description; and I have noticed the peculiarity before; the sunset glows of last winter and spring, whenever I had opportunity to see the sky and watch their early phase after sunset; but crystals of ice being then plentiful in ci the evidence of the mock sun's formation by non-aqueous in the atmosphere was not so strong as now, when it recurred after a long continuance of a summer temperat which has been unusually high. It is also singular and cu that the rosy tint began in the white-glow spot, and sp evenly outwards from it as a centre, as the extent and inten of this remarkable colour grew and increased.

Appearing as the white spot does, when I have seen it, pretty fixed height of not less than about 12° from the horiz soon as the sun has set, it seems difficult to reconcile its pre at such an altitude with a theory of its production by refle of the sun's horizontal rays from fine films or laminæ of flo glassy dust, unless descending equatorial currents, perhap those extremely stable heights may have a sensible inclin downwards from the west, and may tilt the films' under in a direction corresponding with that of the current sl towards the sun?

With regard to the diverging beams, they are also, perl not quite ordinary, irregularly produced straight lines of r tion; but seemed by their symmetry to be connected, at le the origin of the shadow-gaps which formed them, with e ruled stripes or pleats of the cirrus, and of loftier haze, ir case directed, it seemed, nearly east and west. With such bands and stripes directed rather more south-westerly, or a towards the point of winter sunset, and intersected also slightly slanting systems of striation, I constantly notice sky in Newcastle-on-Tyne, during the prevalence last winte spring of the repeated sunset glows, to be for weeks and m more or less constantly and uniformly, but in general w and dimly, streaked and furrowed over. Either an unus steady current was prevailing in the upper air; or else a pe nent current there, and long lines of aërial disturbances trou its streams were made more visible and conspicuous than ordi by exceptional radiation, or some other unusual refrigerating haze-engendering cause, depriving the upper air of its tran ency, during the time of the sky's presenting such un appearances in what Quetelet named and considered to b "stable" or untempestuous upper regions of the atmosphe

Whatever may be the explanation of the streamers and c white glare-spot, observations may perhaps be made of under even more favourable conditions than occurred this ing, and they would then possibly give a little help to arriving at some further conclusions both as regards the cr line or other nature of the haze-causing substance, and as

manner and direction of the motions of the extremely lofty air-currents in which the finely-divided material is suspended.

A. S. HERSCHEL

Collingwood, Hawkhurst, September 20

ON September 27, being on the river about 6 p.m., I noticed the beautiful colour of the sky, which lasted for three-quarters of an hour after sunset. The day had been very cloudy, but not much rain had fallen, and about 4.30 p.m. the sky cleared and the sun shone out. My attention was drawn to the appearance of the sky about 6.15, after the sun had set. Great masses of red appeared in the west on a background of gold and primrose; above this the sky shaded from green into blue; the red colour extended upwards for about 40°, and appeared of various shades, deep red, magenta, and rose colour, the various small clouds which were floating about being pink. This red light gradually broadened out and died away, giving place to deep orange and gold, the latter colour lasting till 6.45.

The water was as gorgeous as the sky above, the reflections of the trees being bright red and purple on a floor of gold. I may add that the red light from the sky was so strong that a rosy hue was thrown on some trees and everything around.

Hurley Mill, September 28 T. M. BROWNE

September Stream of Krakatoa Smoke at Strong's Island

AFTER long delay, owing to the wrecking at Strong's Island of the *Morning Star*, I feel very fortunate in coming into possession at last of a most important record of fact, which I hasten to publish, in the form of an extract from the journal of Miss Cathcart, the young lady missionary labouring at Strong's Island with Rev. Dr. and Mrs. Pease, and well known in Honolulu. It is as follows :—

"*September* 8.—Yesterday there was a very peculiar appearance of the sun. The sky was somewhat cloudy, but not so as to obscure the sun, which was of a silver blue colour, and not so bright but what we could look at it without any trouble. The shadow was the same as in an eclipse. There was no bright sunshine all day."

Although the journal contains no further record on the subject, nor any mention of the red glows which must have followed, it is so precise as to date and as to the phenomena observed as to be of the greatest value in continuing the history of the equatorial smoke-stream from Krakatoa beyond Honolulu and Fanning's Island, to which it had been continuously traced on its long route *viâ* the Seychelles, Cape Coast Castle, Trinidad, and Panama. It was observed by the barque *Southard Hurlburt* some 2000 miles east-south-east of Honolulu on September 3, at Fanning's Island on September 4, and at Honolulu in conspicuous brilliancy on the evening of the 5th. Mr. Frank Atwater, landing at Maalaea, Maui, on the morning of the 5th, observed a wonderful red glow, and marvelled much (having just arrived) if such were the sunrises in these islands. The same morning passengers on the *Zealandia* steaming southwards towards the Line were awakened by *blue* sunlight streaming into their berths. Mr. F. L. Clarke has supplied a report, somewhat imperfect as to date, of an obscured and coppery sun seen at the Gilbert Islands on or about September 7. This would be September 6 in our reckoning, the Gilbert Islands being west of the meridian of 180°.

Now we have the very precise date given by Miss Cathcart, of September 7 (6th) at Strong's Island, or just one day later than at Honolulu, and thirty-six hours later than the late afternoon coppery and lurid obscuration seen at Fanning's Island. Strong's Island is about 2320 miles nearly due west of Fanning's Island. This gives a rate of progress of the smoke-stream of sixty-four miles an hour. It seems proper to reckon time from Fanning's Island rather than from the Hawaiian Islands, as the latter were evidently north of the central course of the stream, and perceived its atmospheric effects half a day later than the former, although nearly on the same meridian.

It is to be specially noted also that the phenomena were characterised by the peculiarities seen at Fanning's Island, as well as at Panama, rather than those seen at Honolulu. Here the obscuration of the sun was so slight as not to have been noticed during the day, nor was any change in its colour observed, except by Mr. and Mrs. H. M. Whitney, who saw its disk *green* at setting on the 5th. At Strong's Island, as well as at Fanning's Island, Panama, Trinidad, and eastward, the sun was heavily obscured, and its light changed to green at low altitudes, and blue when high up. This proves that the heavier thickness of the smoke-stream did not extend so far north as Honolulu, but was confined to a narrow belt near the equator. Fanning's Island is in lat. 2° 40′ N., long. 159° W. Strong's Island is in lat. 5° N., long. 162° 30′ E. The *Zealandia* was perhaps 5° N. when the blue sun was observed. Honolulu is in lat. 22° 17′ N., and received only the clouds fraying off from the edge of the smoke-belt as it swept by to the southward.

The sun's rays were so greatly obscured by the density of the smoke strata in the main belt that they seem there to have failed to produce the marvellous twilight effects which were so conspicuous in Honolulu. All along the line from Seychelles to Strong's Island, we hear of lurid appearances, green sun, blue light, great obscuration, sun easily observed with the naked eye, but hardly anywhere a word about twilight effects, or red glows; while at Honolulu, under the thinner side clouds of the stream, the colour effects in the twilight were amazing.

The topic is an endless one, and I will not prolong. Many ask what is the cause of frequent revivals of the red glows, such as the very fine one of last evening, August 19. It seems merely to show an irregular distribution of the vast clouds of thin Krakatoa haze still lingering in the upper atmosphere. They drift about, giving us sometimes more, sometimes less, of their presence. It is also not unlikely that in varying hygrometric conditions the minute dust-particles become nuclei for ice crystals of varying size. This would greatly vary their reflecting power. This accords with some observations of Mr. C. J. Lyons, showing that the amount of red glow varies according to the prevalence of certain winds. S. E. BISHOP

Biology *v.* Botany

ACCORDING to the regulations of the Cambridge Local Examinations, 1883, junior students can alone take botany, while senior students must take elementary biology instead. What has been the result? Taking the Regent's Park centre as a typical example, for it is a single school of several hundred girls, and sends up probably more than any other school in England, we find that from 1872 to 1882, inclusive, 273 senior students entered, and 191, or 70 per cent. passed in botany. In 1883, however, *none were sent up at all*. If we ask, What is the object of teaching science in schools? the answer is obviously for its educational value. Now this can only be acquired by practical study. Botany is eminently qualified for affording this use, whereas zoology is not. The lady principal of the school in question will not entertain the idea of teaching any branch of science if it cannot be taught practically, and very pertinently asks, "How can I get two to three hundred frogs, and make my girls dissect them? In the first place, the parents would not allow it." Consequently biology becomes a dead letter, and botany is discountenanced by the Syndicate for the elder girls.

On inquiring of a member of the Syndicate, I am informed that the general idea is that the juniors should study botany from this educational point of view, but seniors are of such an age that mere "object-lessons" are no longer necessary, but training in scientific thought is called for. Now, in the first place, it must be borne in mind that, from the pressure of other subjects, it is not generally, if ever, easy to teach science at all adequately in schools; and, secondly, the small amount of botany that can only possibly be taught, even to the elder pupils, is little more than practical descriptions, a certain acquaintance with the leading families of plants, and the general principles of physiology and histology. There is not the time to do more. As an examiner for the College of Preceptors for many years, and having to look over papers from schools, &c., from all parts of England, I can testify to the fact that the standard of botanical teaching is decidedly low. Of course there are exceptions, but the majority, who get less than half marks, show little more than a smattering of the subject. Instead, therefore, of insisting on elder pupils advancing to biology, my own feeling is that it would be decidedly better to encourage seniors to continue the study of botany alone, but more thoroughly. The idea of calling such botany an "object-lesson" will sound somewhat ludicrous to my fellow teachers, who know what teaching practical botany thoroughly really means!

The remedy, therefore, seems obvious. Let the seniors as before pass in botany alone, but of a higher standard if you

will; and leave biology as it is for any who may wish to take up that subject. At present the effect can only be to quash the teaching entirely beyond its first and most elementary stage.

There are not wanting signs elsewhere of the evil effects of the younger school of botanists not recognising the importance of first training students in a thorough course of practical and systematic botany before proceeding to laboratory work. In an examination lately held for a post at Kew, I am informed that two gentlemen who had been trained at Cambridge competed with a gardener for the post. The gardener secured it. *Verb. sap.*

GEORGE HENSLOW

Animal Intelligence

HAVING frequently observed in your columns accounts of remarkable instances of reasoning power in animals, I am tempted to send you the following notes, which may perhaps be not without interest to the readers of NATURE.

A young canary belonging to our family is in the habit of receiving small pieces of biscuit, cake, or such like from the tea-table. The hardness of the biscuit has ever been a source of great annoyance to Dicky. One day, however, after an expectant and close examination of the tea-table, he was offered a piece of hard biscuit. Without making the least attempt to break it, he lifted it from the floor of his cage, and taking it to his water-trough, gently dropped it in, following up the action by patiently stirring it round and round with his beak, until it was in a condition to be eaten. He then carefully removed it and devoured it without any trouble. He now puts every *hard* substance which he deems eatable into the water. He endeavoured to soften sweets in the same way, but finding that the sweet became gradually smaller and smaller, he hastily abstracted it, and has never since put anything of that nature into the water.

An equally interesting case of reasoning power was lately exhibited by our cat. Pussy had lately become the mother of a family of kittens, and was naturally indisposed after the occurrence. She wandered about through the house in a strange manner, as if seeking for something, always, however, keeping within near range of the coal bunkers when they were likely to be required. With a view to finding out what she wanted, the bunkers were left open. The cat immediately entered, and commenced searching diligently among the coals, until she found a piece covered with pyrites. This she proceeded to lick vigorously, returning to the bunker and repeating the operation at regular intervals. On ground sulphur being offered her, she at once forsook the pyrites for that, and ere long, by use of that medicine, regained her usual health.

Zoological Laboratory, University College, Liverpool, September 29

IN the notes on Australian ants forwarded by me by the last mail I forget whether any mention was made respecting an idea that has struck me several times, as to the method in which the antennæ are employed by ants as a means of communicating with each other. That ants utter no audible sound is pretty plainly proved by experiments made with the microphone. It is said that the Ambillidæ give a kind of sharp cry when captured, but the statement requires to be verified. Ordinary ants may be generally spoken of as destitute of any means whereby to utter articulate speech. Beyond the fact that they do not appear to be able to speak, so as to be heard by human ears, the tests resorted to by Sir John Lubbock would go to show that it is extremely doubtful whether ants possess the sense of hearing at all. This, however, does not preclude the possibility, or even the probability, of their being in full power of a means by which they are able to converse. It will be remembered that the antennæ are divided into two separate portions, the *scape* and the *flabellum*. The latter is subdivided into about ten separate segments. Now in this arrangement, by adopting a preconcerted system of signals, all the words of an English dictionary might be expressed.

Let us say that A meets B, and, according to the vocabulary of Formicaria, that a touch with the tip of the antenna of A on the terminal segment of the antenna of B signifies any particular word. A similar touch made on the second segment of the antenna of B indicates another word, and so on. Here there is a means of expressing at least ten different words by taking from the point of the flabellum to its base. If the second point of the flabellum of A is employed as a touching organ, the number of signs that might be conveyed from the one ant to the other would be twenty. If all the segments were thus utilised, a hundred different signs might be interchanged. This is for one antenna only. By utilising the pair this number would be doubled, and by multiplying the number of touches, to express words or plurals of words, also, and by crossing the antennæ so that the right antenna of A touched the left of B, and *vice versâ*, all clearly distinct signals, the vocabulary of these little people would be extended almost *ad infinitum*. Say that the one touch of a segment of the flabellum meant an ant, two touches a pair of ants, and three a multitude; here there exists a means by which complicated ideas might be communicated in a manner somewhat similar to that adopted by the Chinese, by whom a particular sign means a woman, two mischief, and three marital unfaithfulness; or, as in the language of the Australian natives, who employ the term "Yarra" as signifying "flowing," and "Yarra-Yarra" as "ever-flowing." All this would be pantomime, of course; but those who have witnessed a public exhibition of the skill of well-taught deaf-mutes, are aware of the amount of information that can be imparted by the simple use of the ten digits, just half the number of separate conversational organs at the disposal of ants. Nor do persons and nations, well able to speak audibly, fail to avail themselves of the same kind of speech. A Chinaman utters a certain word, but it may mean half a dozen different things, as he moves his fingers to the right or to the left, up or down, or describes some imaginary diagrams in the air.

The above views may seem altogether visionary at first sight, but we have been told so many remarkable stories relative to the instincts displayed by the singularly intelligent creatures under consideration, that no persevering student of their habits will be inclined to say that the use by them of some such code of signals is altogether beyond the range of possibility, even of probability.

It might be as well if naturalists, when watching the meeting of ants, would notice carefully whether the observed touches vary in any particular, and whether any noticeable results followed after, and appeared to be connected with, the variations.

Meteors

I HAVE to record a brilliant series of meteors seen last night (Sunday, July 20) by myself and others. I will describe that seen by myself, as, amid the many splendid meteors I have observed during my sixty years of life, I have never seen one more magnificent. I was walking up and down my "quarter-deck," the carriage-drive in front of my house, which faces due north and south, admiring the glorious tints of the dying day, for we have been having, on a reduced scale, the grand sunsets about which I have already written. I was looking due north, and saw a huge fireball suddenly appear about half way between the horizon and the zenith. It moved slowly and horizontally, leaving a broad trail of red light behind it, as well defined as that emitted by a rocket. The meteor itself was about half the size of a full moon, white, and of the most intense and dazzling brilliancy. It travelled so slowly that I had time to call out, *several* times, to my wife, "Look at that glorious meteor," and she had time to turn round and see it. At about north-north-west it suddenly broke up into six, if not *seven* pieces, but at this moment its light was so intense that I could not be quite certain; six, however, I counted *distinctly*. They did not *fall*, but trailed on in a line after the larger mass, which did not seem diminished by the rupture, and finally, at north-west, they all disappeared. On taking out my watch I found it was just two minutes past six, and as we are a month past our shortest day, you can fancy there was plenty of daylight left to dim its splendour. But it was a magnificent sight, and its intense brilliancy surpassed anything I have seen before.

At 6.30 two friends walked up to dinner. I asked if they had seen the meteor. They said, "Yes, how splendid it was!" I asked, "Could you count the number of pieces into which it broke?" They looked at each other in amazement. "It did not break!" "In what direction did it pass?" was my next question. "From west to east," said one of them; "if you were standing here you could not have seen it; it was low down on the southern horizon, behind your house." I then

found on comparing notes that this one, which they both said was large and extremely brilliant, had appeared about *twenty-five minutes past six*.

At night we attended the Governor's last "reception," prior to his leaving the colony. He was handing my wife to her carriage—I was unfortunately in the house—when another fine meteor illumined the sky. It must have been in the west, or, from the position of the carriage and the buildings, my wife could not have seen it. She says it fell straight down from the zenith, and broke into several pieces. This occurred at 10.45; I had just previously looked at my watch. I also heard of other smaller, though bright, meteors, but did not see them myself. What are we doing, Mr. Editor? Are we going through the tail of a comet? or is cosmic dust igniting? or are these "dire and bloody" portents? Whatever they are, I record them, in the hope that others may have seen and noted them.

British Consulate, Noumea, July 21 E. L. LAYARD

The Milleporidæ

SPECIAL interest is attached to any direct evidence as to the nature of the reproductive organs in the Milleporidæ, the more especially as no traces whatever of such organs have hitherto been discovered. In the absence of any direct evidence it has been concluded that, from the apparent absence of ampullæ, the gonophores probably develop free of the cœnosteum; and this seemed partly borne out by the general resemblance between the zooids of the Milleporidæ and those of the gymnoblastic Hydroids.

On some dry specimens, however, of a new species of Millepora (*Millepora murrayi*, characterised by its extremely laminated and coalescent frond, much and palmately divided at their extremities, and by its minute gastropores, ·25 mm. wide, and its still more minute dactylopores and even surface) from the Philippines, there occur, irregularly and numerously distributed among the young branchlets of the cœnosteum, large receptacles, which, though the absence of the soft parts prevents any absolute confirmation thereof, can leave no doubt as to the true ampullate nature of the generative organs in this family. These receptacles occur either closely, or widely apart, as circular cavities in the superficial reticulations of the cœnosteum, and are covered above by a very thin and porous layer, which is often broken away. When it is thus laid open, the cavity is seen to be about ·75 mm. in diameter. The receptacles are seen on the surface as white, circular, scarcely raised areas about ·5 mm. in diameter, with a small pore in the centre; and they are generally rather numerously placed on one or both faces of the palmated branchlets.

By the discovery of the ampullæ in the Milleporidæ, a complete confirmation is given to the relationship which Prof. Moseley has shown to exist between this family and the Stylasteridæ; and it is seen that the two families are even more closely related than had been imagined. The presence of such a structure seems to bring the Milleporidæ into relationship rather with the calyptoblastic than with the gymnoblastic Hydroids, in spite of the general resemblance of its zooids with the latter. Natural History Museum, South Kensington

To Find the Cube of any Number by Construction

THE following graphical construction for finding the cube of a number may interest more than the mere mathematician:—

Take a triangle ABC, in which suppose A to be the vertical angle and B greater than C. Draw the perpendiculars AD, BE, CF, thus obtaining the pedal triangle DEF; take H the middle point of the perpendicular EG on DF. Then $\tan CDH = \tan^3 CDE = \tan^3 A$. If then we take a triangle with vertical angle A such that $\tan A = n$, we see that $\tan CDH = n^3$. The proof of the above result is quite elementary.

The Failure of the Parsley Crop

WOULD you permit me to ask some subscribers to your paper if it be possible to account for the total failure of the crop of parsley this and last year. Is it owing to any known insect or what? The parsley comes up well, grows to about one inch in height, then begins to dwindle and get yellow, and the whole summer remains about half an inch high, the only green part being the crown. All the market gardeners are in the same position as myself, only one having a crop, and this was sown in freshly cultivated earth. I have carefully examined leaves and roots under the microscope, but can discover no cause for this disease. Have any of your subscribers been troubled in the same manner, and can any one suggest a remedy? W. H. C. B.

Cheltenham, September 23

Wasps as Fly-Killers

YOUR correspondent at p. 385, vol. xxx., may be informed that in this part of the world wasps enter dwellings by the open windows in summer-time, and hunt house-flies unmercifully, leaving the dead flies in hundreds on the floors, ready to be swept into a dustpan. This occurs only in the country, and where wasps' nests are near by. Westwood quotes from St. John's "Letters to an American Farmer" that: "The Americans, aware of their (wasps') service in destroying flies, sometimes suspend a hornets' nest in their parlours" (Introduction to "Modern Classification of Insects," ii. p. 240, foot-note). GEORGE LAWSON

Dalhousie College, Halifax, Nova Scotia, September 8

GEORGE BENTHAM

WE recently announced the death of the veteran botanist, George Bentham, when within a few days of his eighty-fourth birthday. His life, from a very early age, was one of incessant mental activity, and of much change and vicissitude during its three or four first decades. Through his birth, connections, and various residences on the continent of Europe, as well as in England, he became acquainted with many men famous in literature, science, and art, and his career is rendered especially notable from its intimate association with his uncle Jeremy, the jurist, in the arrangement of whose papers and preparation of whose works for the press he was actively engaged for not a few years, and with whom he resided on the most intimate terms as companion and secretary till the death of that relative in 1832. This and the scientific value now attached to the "pedigree" have suggested the expediency of entering with some detail into the family history and early life of Mr. Bentham (for most of which we are indebted to information imparted by himself) before detailing his botanical career and writings.

About the year 1750 Jeremiah Bentham, an attorney or solicitor, one of a family of scriveners who, as fathers and sons, had inhabited the Minories since the beginning of the seventeenth century, migrated to the West End of London, purchasing property in Queen's Square Place and Petty France (now York Street, on the south side of Birdcage Walk, St. James's Park). He had two sons: the elder, Jeremy, the well-known writer on Jurisprudence, the younger, Samuel (subsequently Sir Samuel), father to George, the botanist. Samuel devoted himself to the study of naval architecture, and at the age of twenty-two visited the arsenals of the Baltic for the purpose of improving himself. From thence he travelled far into Siberia, and became intimate with Prince Potenkin, who induced him to enter into the service of the Empress Catherine, at first in a civil, and afterwards in a military, capacity. In the latter he took a distinguished part in a naval action against the Turks on the Black Sea. For this he received the Cross of St. George, and was given the command of a regiment quartered in Siberia, which enabled him to penetrate eastward to the frontier of China. After ten years of absence he returned to England, and was shortly afterwards promoted to the rank of general. The death of Catherine followed soon after, when he was offered employment in England by his friend Earl Spencer, then First Lord of the Admiralty, who was anxious to avail himself of Gen. Bentham's ingenuity and experience in

improving the civil branch of our naval system. This he accepted, resigning the Russian service, and attained the post of Inspector-General of Naval Works. His son has been heard to say that amongst other improvements introduced by Gen. Bentham into the dockyard were the steam sawmills and the machinery for the eccentric turning of blocks, through his employment of the late Isambard Mark Brunel, whom he brought over to England.

In 1796 Gen. Bentham married the eldest daughter of Dr. George Fordyce, F.R.S., the well-known physician and author. Mrs. Bentham was a woman of great ability and energy; she had actively aided her father in the preparation of his works, and with still greater perseverance she devoted herself to assisting her husband in his arduous labours, drawing up as well as writing out his voluminous reports to the Admiralty, and accompanying him on his visits of inspection to the dockyard, which were often of several months' duration. Up to the age of eighty she wrote a most beautiful hand, and it is within the recollection of readers of this article that letters in the *Times*, under her signature, when she was considerably over ninety years of age, appeared during the Crimean War, urging the introduction of improvements in our war material, especially great guns, which her late husband had suggested.

It was during one of the annual inspections of the Portsmouth Dockyard that George was born, at Stoke, then a village near Portsmouth, and now absorbed in that town. He was the second son, and had three sisters, one of them older than himself. All were forward children: on their fourth birthdays the two elder sisters made the clothes they wore on those days and wrote out a list of their possessions; and before he was five years old, George wrote copies, enjoyed reading Miss Edgeworth's "Easy Lessons" with his brother, and began to study Latin. The whole family were taught reading by the words, not letters or syllables.

In 1805 Gen. Bentham was sent by the Admiralty on a mission to St. Petersburg, having for its object the building in Russia of ships for our navy, and he took his family with him. There they remained for two years, during which time the education of the children was intrusted to a talented Russian lady, who could speak no English; and the young people, showing a remarkable facility for the acquisition of languages, were able before leaving to converse fluently in Russian, French, and German. Latin was acquired under a Russian priest, and, at six years of age, music, to which George subsequently became passionately attached, was commenced.

War between England and Russia breaking out in 1807, Gen. Bentham was recalled. The homeward route was by Revel and Sweden, and the voyages were notable. At Revel they embarked for Stockholm in a Russian frigate, a bad sailer, with a crew hardly any of whom had before been at sea; and, after driving backwards and forwards in the Baltic under continuous gales, they landed on the fourteenth day at Carlscrona! In Sweden they were detained several weeks, long enough for the two brothers and their elder sister, by dint of perseverance and hard study, to learn enough of Swedish to converse in that language and read it with tolerable ease. From Gothenburg they sailed for Harwich in a wretched craft, and, after beating about the North Sea in a succession of tempests, arrived on the fourteenth night, when the crew took the boats and hastened ashore, leaving the Benthams till the following midday with no other food but rejected bits of biscuit picked up wherever they could be found.

In England the family settled at Hampstead, whence the father went daily to his offices at the Admiralty and Somerset House, whilst George and his brother pursued their studies. These, then and ever afterwards, were conducted by private tutors, and it was a life-long source of regret to George that he had never been at school or college. This, in his opinion (and not his alone), accounted for an habitual shyness and reserve that often caused him to be misunderstood, and credited with motives or sentiments that were foreign to his disposition and character. Much of his time was spent at Berry Lodge, a house and property which his father had bought between Gosport and Alverstoke, where the summer months were passed, and which still belongs to the family. It was from here that he was once taken by his father on a visit to Lady Spencer at Ryde, and met at her house John Stuart Mill—then on a visit there—a boy of six, in a scarlet jacket and nankeen trousers buttoned over it, and who was then considered a prodigy. Bentham has described him as wonderfully precocious, a Greek and Latin scholar, historian, and logician, fond of showing off, and discussing with Lady Spencer the relative merits of her ancestor the Duke of Marlborough and the Duke of Wellington, he taking the part of the latter.

The year 1814 opened upon a period of great excitement throughout the Continent; the invasion of Russia by Napoleon and the burning of Moscow were naturally matters of intense interest to the Bentham family. The boy George, then only thirteen, now budded into an author, commencing with his brother and sister the translation of a series of articles from a Russian paper, detailing the operations of the armies, which were contributed to a London magazine of ephemeral duration. He gloried in the reverses and final abdication of Napoleon, and was presented to the Emperor of Russia by his father on the visit of that monarch to the naval establishment at Portsmouth.

Peace being proclaimed, the Bentham family went to France, and prepared for a long residence in that country; they resided first at Tours, then at Saumur and Paris, during the eventful period that extended from the return of Napoleon to his final overthrow. Young Bentham kept full journals of all that passed, interspersed with anecdotes relating to the forced exile of Louis, the defeat of the Emperor, the restoration of the Bourbons, the conduct of the allies, the execution of Ney and Labedoyère, the condition of the city of Paris, and the prominent part taken in the politics of the day by Walter Savage Landor, who was intimate with his family. Moreover, he seems to have been able at this early age to enjoy and even take his part in the society of the eminent men of the time and the *salons* of the leaders in literature and science, the Duc de Richelieu, Talleyrand, the Comte de Damas, Jean Baptiste Say, the aged Mme. Andelan (the daughter of Helvétius), were amongst the intimate friends of the family; as was Baron Humboldt, who took warmly to the lad, encouraging especially his taste for geographical science, giving him introductions to libraries and to individuals who could aid him in the preparation of a work which he had begun on the data of physical geography.

In 1816 Gen. Bentham organised what may be called a caravan tour of France for himself and family, having for its objects partly unceremonious visits to his many friends in the provinces, and partly the leisurely inspection of the great towns and other objects of interest. The *cortège* consisted of a two-horse coach fitted up as a sleeping-apartment, a long, two-wheeled, one-horse spring van for himself and Mrs. Bentham, furnished with a library and piano, and another, also furnished, for his daughters and their governess. The plan followed was to travel by day from one place of interest to another, bivouacking at night by the road, or in the garden of a friend, or in the precincts of the prefectures, to which latter he had credentials from the authorities in the capital. In this way he visited Orleans, Tours, Angoulême, Bordeaux, Toulouse, Montpellier, and finally Montauban, where a lengthened stay was made in a country-house hired for the purpose. From Montauban (the *cortège* having broken down in some way) they proceeded, still by private conveyances, to

Carcassonne, Narbonne, Nîmes, Tarascon, Marseilles, Toulon, and Hyères.

It was during this tour, when at Angoulême, that Bentham's attention was first turned to botany, and it fell out on this wise :—His mother, who was fond of plants, and a great friend of Aiton at Kew, had purchased a copy of De Candolle's "Flore Française," which was then just published. Young Bentham took it up accidentally, and was struck with the analytical tables for the determination of the affinities and names of plants, which exactly fitted in with the methodising, analysing, and tabulating ideas which he had derived from his Uncle Jeremy's works, and had endeavoured to apply to his own geographical tables. He at once went into the back-yard of the house, and, gathering the first plant he saw, he spent the whole morning studying its structure with the aid of the introductory chapter of the "Flore," which treated of elementary botany, and succeeded in referring it to its natural order, genus, and species. The plant, *Salvia pratensis*, was not an easy one for a beginner, owing to the irregularity of the flower and abnormal character of the ovary and stamens. His success led him to pursue the diversion of naming every plant he met with in future.

At Montauban, near Tours, where the family resided for many months, Bentham spent what he always regarded as the happiest period of his life ; he was entered as a student of the Faculté de Théologie. at Tours, followed with ardour the courses of mathematics, Hebrew, and comparative philology (the latter a favourite study in after-life), and at home occupied his time with music, Spanish, drawing, and botany, whilst, during the holidays, dancing was his delight ; it was a favourite boast that at Montauban he attended thirty-four balls between Twelfth-night and Mardi-gras, of which thirteen were consecutive, and lasted from nine at night to the same hour on the following day.

The appearance of the "Dictionnaire d'Histoire Naturelle," a course of lectures under Benedict Prevost, and De Candolle's general works on the structure and classification of plants, first opened his mind to scientific botany, and induced him to take up the study of exotic plants, to which he devoted himself till 1820, when he took to the amusement of shooting and stuffing birds. At this period, too, John Stuart Mill resided in his father's family for seven or eight months, and it was probably due to this that Bentham was diverted to the study of philosophy, and at the age of twenty began a translation into French of his uncle's "Chrestomathia," which was published in Paris some years afterwards. Here, too, he began the study of Lamarck's works, with the "Système analytique des Connaissances positive de l'Homme," only to give it up in disgust on reading "Dieu créa d'abord la matière," followed by the statement that nature was the second thing created, and this produced everything else. Sliding down from great things to small, a fit of entomology supervened, and he commenced tabulating observations on insect life as he had his geographical and philosophical facts and ideas.

The next phase of Bentham's Protean life was that of a practical estate-manager and farmer, his father having bought a property of 2000 acres. that of Restinalières, near Montpellier, and given over the management of it to his now only son, for he had lost his eldest through an accident some years before. Into this work Bentham threw himself with ardour, and now his methodical habits, close application, and familiarity with French country life stood him in good stead. The farms and vineyards rapidly improved, and were very profitable. Still he found time for his favourite pursuits, his holidays were spent in botanical excursions to the Pyrenees and Cevennes, and his spare hours at home in logic and the preparation of a French edition of his uncle's essay on Nomenclature and Classification. Here, too, he wrote his own first work of importance, "Essai sur la Nomenclature et Classification des Arts et Sciences," which was published in Paris, and established his position in France as an acute analyser, clear expositor, and cautious reasoner.

In 1823 Bentham was sent to England for the purpose of purchasing agricultural implements and obtaining information as to improved methods of farming that might be introduced into the Montpellier estate. On arriving in London he was asked by his uncle to visit him, bringing his translation of the "Chrestomathia." This invitation, the attractions of English scientific and literary society, and the fact that provincial jealousies threw every obstacle in the way of the introduction of improvements into the Restinalières estate, led ultimately to the abandonment by his father of the latter (in 1826), and the return of the Bentham family to England.

On his arrival in London he was at once received into the best literary and scientific society ; he attended the breakfasts and receptions of Sir Joseph Banks, and studied in his library and herbarium, and that of the Linnean and Horticultural Societies, and formed life-long friendships with Brown, Lambert, Don, Sabine, Menzies, &c. During a tour through England and Scotland, taking with him letters of introduction to the leading botanists there, he became acquainted with Sir James Smith, Dawson Turner, Graham, Greville, Hooker, and many others. It was during this tour that he formed a friendship with the late Dr. Arnott (subsequently Professor of Botany in Glasgow), with whom he made, in 1824, an extended journey into the Pyrenees, which resulted in his first botanical work, "Catalogue des Plantes indigènes des Pyrenées et de Bas-Languedoc, avec des Notes et Observations" (Paris, 1826).

On the settlement of the family in London a new career was opened to Bentham, his uncle Jeremy having invited him to devote much of his time to aiding him in the arrangement and preparation of his MSS. for the press, accompanying the invitation with assurances that he would provide for him at his death. The proposal of aiding his uncle was congenial to him, but not the accompanying one, for he was now desirous of seeking a serious profession that would lead to independence ; and after many embarrassing interviews on the subject with his uncle it was arranged that he should enter Lincoln's Inn and study law, whilst devoting some morning hours to his uncle, besides dining with him twice a week and writing for him afterwards from 8 to 11 p.m. In one shape or another this arrangement of working with and for his uncle lasted till the death of the latter in 1832 ; when, owing to the many foolish and fruitless speculations of the great jurist, the extravagant sums spent by his executors on the posthumous publication of his works, and some irregularity in his will, Bentham found himself in possession of the house in Queen Square Place, but with less property than he should have received. His father's death, however, in the previous year, had rendered him in a measure independent.

From 1826 to 1832 Bentham's life was one of incessant activity. Besides his irksome labours for his uncle, in whose ideas he did not at all participate, and many of whose acts he regretted, he had the editing and often rewriting of his father's (now Sir Samuel Bentham's) voluminous papers on the management of the navy and the administration of the dockyards. His legal studies were sacrificed to logic and jurisprudence ; the fruits of the former being the publication of his "Outlines of a New System of Logic, with a Criticism of Dr. Whateley's Elements of Logic" (London, 1827), in which the doctrine of the quantification of the predicate is for the first time clearly set forth. This remarkable work fell still-born from the press ; only sixty copies were sold, when the publishers became bankrupt, and the stock was seized and went for waste paper. It was not till 1850 that the fact of its containing a discovery was recognised (*Athenæum*, December 31, 1850) ; this led to a sharp dispute as to Sir

William Hamilton's claims to the same, and which was ended by a verdict of Herbert Spencer's in the *Contemporary Review* (May 1873) in favour of Bentham.

In jurisprudence two subjects deeply engaged his attention—one was codification, in which he entirely disagreed with his uncle, and his paper on which attracted the attention of Brougham, Hume, and O'Connell; the other was the laws affecting larceny, his suggestions on which he submitted to Sir Robert Peel, *apropos* of his Bill for the consolidation of the criminal law. Of this Peel thought so highly that he wrote a complimentary letter to its author, informing him that his remarks should be fully considered and submitted to Sir John Richardson, to whom the Bill was referred. Brougham also (to whom his uncle showed the paper) wrote a letter of eighteen pages of remarks on it. These and a pamphlet on the "Law of Real Property" are Bentham's chief contributions in his adopted profession. Of practice he had very little; he got his first brief in 1832, and, as junior counsel, bewigged and begowned, followed his leader when called for; but, being overcome with nervousness, he cut short his argument, and had the mortification of hearing the counsel for the opposite side say that "a more preposterous speech it had not been his fortune to hear during a long course of practice"

In botany Bentham was more at home than in the courts. In 1828 his herbarium arrived from France, and in the same year he was elected a Fellow of the Linnean Society, and joined with delight its reunions, attending its meetings punctually, its anniversary dinners, and those of its club. The return of Wallich from India with the enormous collections of the East India Company which first made known the flora of the Himalayas, Burmah, and many other parts of that vast empire, gave him occupation in the study and publication of various intricate genera and natural orders of plants. Of these writings, his "Labiatarum, Genera and Species" was the most important; this large family having been in a state of utter chaos before Bentham brought his remarkable powers of generalisation and description to bear upon it.

In 1829 Bentham finally gave up the law for botany, and amongst other labours accepted the honorary secretaryship of the Horticultural Society, which was in a perilous condition of debt and dissension. From these he extricated it with perfect success, and, aided by his friend Lindley, the assistant secretary, raised it to a flourishing condition financially and scientifically, and which it has never since approached.

In 1833 he married the daughter of the late Right Hon. Sir Harford Brydges of Boultibrooke, formerly Ambassador at the Court of Persia, and in 1834 removed to his late uncle's house in Queen Square Place, the site of which is now occupied by the "Bentham wing" of the "Queen Anne's Mansions." There he resided till 1842, when, with the view of providing better accommodation for his now extensive herbarium and library, and devoting himself more exclusively to science, he removed to Pontrilas House in Herefordshire, where he revised the *Labiatæ*, and elaborated the great families of *Scrophularineæ*, *Polygoneæ*, and others for his friend Alphonse de Candolle's continuation of the "Prodromus Systematis Naturalis Regni Vegetabilis."

In 1854, finding that the expenses of his collections and books were exceeding his means, he determined on presenting the whole to the Royal Gardens at Kew (they were valued at 6000*l.*), and returning to London; at the same time he entertained the idea of abandoning botany, with characteristic modesty regarding himself as an amateur who had hitherto pursued the science rather as an intellectual exercise in systematising, than as a scientific botanist, who, in his opinion, should unite a competent knowledge of anatomy, physiology, and of Cryptogamic plants, to skill as a classifier and describer of Phanerogams. He yielded, however, to the entreaties of his friends, the late Sir W. Hooker and Dr. Lindley, coupled with the offer from the former of access to his own private library and herbarium, and a room in Kew where his own was placed, backed by the request that he would inaugurate the series of colonial floras that was planned at Kew, by elaborating that of Hong Kong. Consequently, in 1855 he again took up his residence in London, first at Victoria Street, and latterly at 25, Wilton Place, and for the remainder of his life, till disabled by age, he almost daily throughout the year, except during autumn excursions to the Continent or visits to friends in Herefordshire, repaired to Kew and occupied himself exclusively with descriptive botany from 10 a.m. till 4 p.m.

The Hong Kong flora finished, Bentham took up that of Australia, and, aided by the observations, collections, and numerous discoveries of his active and able correspondent, Baron Mueller, of Victoria, he, single-handed, completed it in 1867 in seven octavo volumes, containing about 7000 species, the most extensive exotic flora ever brought to a conclusion. Meanwhile, the plan of a general work on Phanerogamic plants had been on various occasions discussed by Dr. Hooker and himself; at first it was proposed to confine it to carpology, but it finally assumed shape in a critical study and description of the genera of plants, founded on all available characters, for which his herbarium and the Hookerian offered unrivalled resources. This work, entitled "Genera Plantarum ad Exemplaria, imprimis in Herbariis Kewensibus servata, definita," was commenced in 1862 and concluded in 1883, the greater portion of it being the product of Bentham's indefatigable industry.

The only material break in Bentham's work at Kew was his acceptance of the presidency of the Linnean Society, which he held from 1863 to 1874, and to the duties and interests of which he devoted his time, his energies, and his purse, with characteristic singleness of purpose. He combined with the duties of President those of Secretary, Treasurer, and Editor of the botanical parts of the *Transactions* and *Journals*, spending a part or the whole of one day a week in the Society's rooms during the eleven years of his presidency. On the final transference of the Society's collections, library, and portraits from the rooms in old Burlington House to those they now occupy, he arranged the whole himself, classifying the books, and literally with his own hands placing them on the shelves they now occupy. His presidential addresses were remarkable for their grasp and wide range, and those who knew him only as a systematist and descriptive writer were surprised to find the great powers of analysis and the sound judgment he displayed in discussing evolution and its bearings, the writings of Haeckel, geographical distribution, the condition and prospects of fossil botany, deep-sea life, abiogenesis, methods of biological study, and the histories and labours of the Natural History Societies and their journals, and the scientific periodicals of every civilised quarter of the globe.

On the conclusion of the "Genera Plantarum" in the spring of 1883, his strength, which had for some years shown signs of diminution, suddenly gave way, and, after several ineffectual attempts to resume his studies, his visits to Kew ended, and, lingering on under increasing debility, he died of old age on September 10 last, when within a few days of his eighty-fifth year, leaving no family, and directions that his funeral was to be a strictly private one.

The above sketch conveys no idea of the prodigious amount of systematic and descriptive work in Phanerogamic botany that Bentham accomplished. In the "Genera Plantarum" there is hardly an order of any importance that he did not more or less remodel. His labours on the Compositæ, Gramineæ, Cyperaceæ, and Orchideæ are especially noticeable, and he contributed

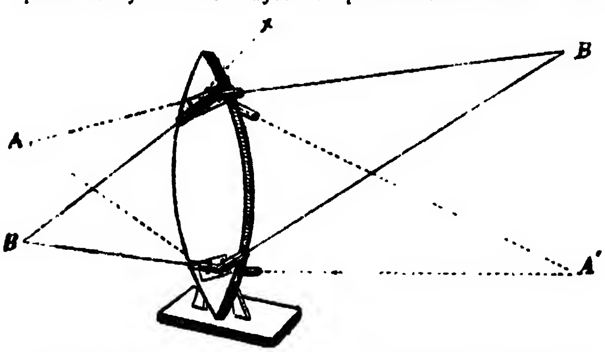
masterly essays upon these and others to the Linnean Society. His treatises on the Leguminosæ are no less exhaustive and valuable; and there is not a temperate or tropical region of the globe whose floras have not been largely elucidated by him. It may safely be affirmed that for variety and extent of good work of the kind he had no superior. The distinctive qualities of his descriptions are—scientific accuracy, good arrangement, precision of language, lucidity, and the discarding of what is superfluous. In these respects he has had no superior since the days of Linnæus and Robert Brown, and he has left no equal except Asa Gray.

Of his amiable disposition, and his sterling qualities of head and heart, it is impossible to speak too highly: though cold in manner and excessively shy in disposition, he was the kindest of helpmates and most disinterested of labourers for others.

Of recognition by foreign Academies Bentham had his full share, including that of Corresponding Member of the Institute of France. His election into the Royal Society was not till late (1862). It should have been in 1829, when he was proposed by R. Brown, and at his recommendation withdrawn, along with other scientific candidates, who thus showed their dissatisfaction at the Society's election of a Royal Duke to the President's chair. He, however, received the Royal Medal of the Society, and in 1878, on the completion of the Australian flora, the Secretary of State for the Colonies, unsolicited, recommended him to Her Majesty for the Companionship of the Order of St. Michael and St. George.

A MODEL LENS FOR USE IN CLASS DEMONSTRATIONS

IN using diagrams or models as aids in teaching, this question constantly arises—How far may we represent Nature diagrammatically without producing in the mind of a student one-sided and false impressions? I have myself endeavoured to follow this rule: that, if a complicated object or phenomenon is to be studied, we may simplify this, and bring out many salient features, with a diagrammatic representation; this must, however, only be looked upon as a stepping-stone to a more complete study of the object or phenomenon itself. The



model of a lens to be described I have found of much service in lecturing, antecedent to a demonstration of the passage of luminous rays through actual lenses.

This model may be constructed out of the simplest materials, and should cost but two or three shillings. It consists of a piece of deal board cut in the shape of the cross-section of a biconvex lens, and fixed to a stand of wood (see diagram). Four small squares of board, x, are fixed in the positions indicated, two on either side of the lens. Glass tubes bent at obtuse angles are fixed to these by staples, and can rotate with them on the screws by means of which the squares are fixed to the lens. Two pieces of string to represent visual rays are then passed through the tubes A A′ and B B′. The theory of the use of this model will be at once apparent. A ray of light passing through a lens of a given curvature and density will practically (this is not absolutely true) be bent at a given angle, whatever be the direction of the ray, so long as it passes through the same part of the lens. In the model this constant degree of bending is given to the string—representing the ray of light—by the bent tubes. These, rotating on the lens, allow one diagrammatically to represent the rays passing through it in any desired direction.

Taking the string B B′, for example, and holding it at these two points in the two hands, and keeping the string taut, it will be found that in shifting the point B—representing a luminous point in any direction, B′ will shift until it occupies the position of the corresponding focus. By shifting the string it is possible to demonstrate the focal points of parallel, diverging, and converging rays, either parallel to the axis of the lens, or on secondary axes. Then, by using at the same time the string fixed to the other side of the lens A A′, the formation of an image may be shown. Grasping with the two hands A and B, an assistant holding A′ and B′, it will be seen how by this lens an inverted image is produced. Bring the points A and B nearer the lens, keeping them, however, at the same distance apart, and the points A′ and B′ will recede from the lens and from each other, showing how the image of the nearer object is formed farther away from the lens, and is larger in size. On the other hand, if A and B be pulled away from the lens, A′ and B′ approximate to it and to one another.

In working the model the squares should rotate easily, and the strings must always be held taut. For lecture-room purposes the lens should be about two feet high, and the strings may be coloured. On the same principle I have constructed models of other lenses or lens combinations.

JOHN B. HAYCRAFT

Physiological Laboratory, Mason College, Birmingham

THE ELECTRICAL EXHIBITION AT PHILADELPHIA

[FROM A CORRESPONDENT]

TO one who has visited the various electrical exhibitions held in recent years in the chief European cities, the Exhibition now open in the city of Philadelphia might seem a little disappointing from the absence of novelty in the exhibits, though replete with objects of interest for all to whom this class of show is not familiar. As might be expected, the strong point of the Philadelphia show is electric lighting; and the building—a temporary structure erected close to the depot of the Pennsylvania Railroad Company on the west bank of the Schuylkill—presents both interiorly and exteriorly a blaze of light. The array of dynamo-machines is remarkably complete. Edison leads the way with a variety of machines, including one "Jumbo," of the same type as, but rather smaller than, the pair of machines in use at the Holborn Viaduct lighting station. There are also a large number of Weston's machines, and a very valuable exhibit by the Thomson-Houston Company. The machines of the latter company are quite unique amongst dynamos; one of them can maintain sixty arc lights on one circuit, though there are but three coils on its armature. Other dynamos are shown by Ball, Hockhausen, Van Depoele, and McTighe. There are several excellent arc lamps, possessing novelty, however, in matters of detail only. A great show of incandescent lamps is made by the Edison Company, and also by the Weston Company. The latter has some remarkable lamps with filaments sixteen inches in length prepared from a new parchment-like substance, of which samples are shown. These lamps are from 100 to 200 reputed candle power.

Electric motors are exhibited by several inventors.

The little Griscom motor and the Cleveland motor are of course present, driving sewing-machines and fans. Edison contributes also some small motors of excellent finish. Amongst larger machines there is one by Daft and one by Elihu Thomson. But by far the most important of all exhibits of this class is that of Mr. F. J. Sprague, which shows a very great advance on anything hitherto accomplished. Mr. Sprague appears to have succeeded in producing a motor which runs at a uniform speed whatever its load. It is employed in driving a small loom.

In telephones there is not much new. The Clay Telephone Company exhibits its system, with a remarkably simple and efficient receiving instrument. Beyond this there is absolutely nothing new. The chief interest centres on the historic exhibitions of Elisha Gray, Graham Bell, A. E. Dolbear, and Van der Weyde. The remarkable telephones of Daniel Drawbaugh are not yet exhibited to public gaze on account of pending legal proceedings.

In telegraphy the sole novelty is the marvellous multiplex telegraph of Delaney, based upon the principle of La Cour's "phonic wheel," and capable of transmitting seventy separate messages simultaneously through a single wire.

Passing on to other exhibits, it should be mentioned how Messrs. J. W. Queen and Co. display a very large collection of imported apparatus, including the finest instruments of Elliott Brothers, Carpentier, Breguet, Hartmann, and Edelmann. Some excellent measuring-instruments by the Electric Apparatus Company of Troy, N.Y., are also shown. A collection of a curious and instructive nature was exhibited by the U.S. Patent Office, consisting of the historic models sent by inventors. Here may be seen the original Edison telephone, the original Brush dynamo, the original Edison lamp, and many other similar objects, including many old forms of electric motor dating from the years 1840-50. A special effort has also been made to get together a complete modern library of books bearing on the science of electricity. Some six thousand volumes have in this manner been procured, and form a valuable collection.

The Franklin Institute of Philadelphia, which has organised this Exhibition, must be congratulated on the energy and enterprise which it has put forth. It would be impossible to get together a collection of apparatus more thoroughly representative of the solid progress made in electro-technics on the American continent. Though the Exhibition is yet far from complete, it has become much more so since its opening on September 2. It will remain open until October 11.

A NEW APPLICATION OF INDIA-RUBBER[1]

IF iron takes the lead among articles of modern industry in the extent and number of its applications, it yet falls short of india-rubber in their variety. This latter article, indeed, promises soon to attain a universal diffusion. Its industrial career, though little more than just begun, already outstrips that of most substances that were first in the field.

The mere enumeration of its qualities would suffice to account for the diversity of its applications. It possesses so great an elasticity that by this quality alone it adapts itself to a thousand different uses—brace-bands, garters, sides of boots, &c.

Observe how, if not the lightest, india-rubber is at least the most powerful reservoir of mechanical energy known. It lends itself most readily to the restitution, under the form of mechanical labour, of the energy imparted to it by tension, and this restitution may be effected with remarkable quickness. It is owing to the relative lightness of india-rubber considered as an accumulator of energy, and, above all, to its power, that the exactness of the principle of "heavier than air" may be demonstrated on a small scale.

From an electrical point of view, india-rubber acts as a better insulator than gutta-percha, and is, indeed, one of the best insulating bodies known. At the same time that its specific inductive capacity is weaker than that of gutta-percha, it does not become plastic at a moderate temperature. These properties render it an excellent insulator in electrical applications: submarine and subterranean telegraphy, electric light, transmission of force, &c. While it insulates better than gutta-percha, the conductor, where india-rubber is used, does not run the risk of being put out of centre, as is the case sometimes with gutta-percha.

India-rubber is known to oxidise under exposure to air and light; above all, under alternations of dryness and damp. By subjecting it, however, to a special operation, called vulcanisation, a product is obtained which maintains its flexibility at low temperatures, resists heat much better, does not oxidise in air, and absorbs less water. It is especially under the form of vulcanised india-rubber that its applications are numerous.

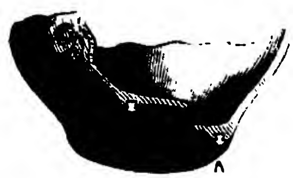
FIG. 1.—Position in which household utensils furnished with india-rubber may be placed without falling.

There is, finally, a third form of india-rubber, no less useful, that of ebonite, or hardened india-rubber, a form which combines with its lightness and great electrical resistance, the further advantage of resisting acids, and which is therefore exclusively employed when vessels for the electric pile or other reservoirs of a light and not readily brittle character are wanted. Like a new Proteus, india-rubber is thus seen to adjust itself to the ever more numerous and pressing demands of modern industry.

To turn now to the new, curious, and original application an idea of which it is the object of this notice to convey. The aim of the inventor, whose name unfortunately has not reached us, has been to take advantage of the great mutual adherence of a soft and a hard body. It is by the utilisation of this relation that the inventor has originated quite a series of household objects in earthen-

[1] From *La Nature*.

ware, porcelain, glass, &c., which manifest a remarkable adherence to the body supporting them, and this result he has obtained by the very simple expedient of securing to the lower part of all kinds of goblet objects (Fig. 2) a groove, A A, in the form of a swallow-tail, into which is lodged a band of red india-rubber, a variety of vulcanised india-rubber, forming, when deposited, a kind of circular cushion. Objects furnished in this manner are almost incapable of falling from their places. They may be placed on a wooden table, and the table be inclined (Fig. 1) from 45 to 50 or even 60 degrees without upsetting any of them. The most direct and immediate use offered by the properties which a vessel so provided with india-rubber thus acquires is evidently in the shipping service. At the Fisheries Exhibition of last year in London, and at the Health Exhibition of this year, the inventor has displayed a little barque, the bridge of which is entirely covered with dishes, plates, &c., all furnished in the manner described, and the barque, floating in a basin, may be



. 2.—Arrangement of the india-rubber covering in a swallow-tail A A, provided at the base of the object.

tossed to and fro in every direction without displacing a single piece.

All who have been on long voyages at sea know the disagreeable and painful impression produced by the screen of cord laid along the table to prevent the glasses and bottles from falling.

As an accessory advantage possessed by the undisplaceable india-rubber dishes may be reckoned the less noise they occasion, and the less risk of breaking they run on being clapped down carelessly or hastily on the table. Washhand basins and water-pots may likewise be advantageously constructed with the india-rubber band.

Invalids in bed, and compelled to eat from a board placed more or less horizontally across the bed, and children, so apt to upset glasses and bottles, will both find their advantage in the undisplaceable contrivance. We have thus a simple, ingenious, and useful application of india-rubber, which we thought it incumbent on us to place before our readers.

NOTES

In the Daily Weather Report of the Meteorological Office for Friday last, there appears a note of some importance on the temperature of the Gulf Stream. A comparison has been made between returns from 28 ships, containing 116 recent observations, with the data in the charts of the Atlantic sea-surface temperature (recently published by the Office), of the area which lies, roughly speaking, between the latitudes of the North of Ireland and of Bordeaux respectively, and extending half way across the Atlantic. It appears from this comparison that during the past summer the ocean temperature in the course of the Gulf Stream was abnormally high, in June the whole of the above-mentioned area being about 3° above the mean, in July the half of the area nearest to the British Isles being about 1°·5 and in August about 1° higher than the mean. It is to be hoped that similar comparisons will from time to time be given by the Meteorological Office, so that the point may be investigated which was long ago suggested by the late General Sabine, as to there being possibly a connection between the temperature of the tropical and sub-tropical waters of the Atlantic and the weather of Europe which followed, and to which we drew attention some years ago (NATURE, vol. xxi. p. 142).

SIR WILLIAM THOMSON lectured on Monday night, under the auspices of the Franklin Institute, at the Academy of Music, Philadelphia, on the "Wave Theory of Light," to a large audience.

GEN. PITT-RIVERS, as Inspector of Ancient Monuments, has issued a very careful and detailed report on his excavations in the Pen Pits, near Penselwood, Somerset. These pits are on the borders of Wilts, Somerset, and Dorset, and consist of a number of hollows in the surface of the ground of various forms and sizes, without order or regularity in their distribution. They cover a tract of high land of greensand formation, the area thus originally covered having been estimated at 700 acres. Various conjectures have been made by antiquaries as to their use, some maintaining that the pits are the remains of a great British city, or formidable series of fortifications; if so, as Gen. Pitt-Rivers points out, it would upset all our conclusions as to the social and political condition of the Britons, and of the extent of the pre-Roman population of these islands. Last autumn Gen. Pitt-Rivers carried out a series of excavations, cutting a section right across the pits in the parts most likely to yield remains of any possible inhabitants. Not a bit of pottery the size of a pea, he tells us, was found, and no indication whatever that these pits have ever been used as habitations. Ample evidence, however, was found that the pits were used as quarries, from which the inhabitants obtained grind-stones or quern-stones. The remains of quern-stones were found, all bearing marks of having been tool-dressed, and in the villages around many such stones are met with, all of them stated to have been obtained from the pits. It is to be hoped that the very careful piece of work thus performed by Gen. Pitt-Rivers, and his report, will set the question permanently at rest. Several plates of sections, plans, &c., accompany the report.

A COMMISSION of five French medical men have reported on their investigations as to the real nature and action of the cholera poison. The substance of their report as it appears in the *Times* is as follows:—"The initial lesion of cholera takes place in the blood. It essentially consists in the softening of the hæmoglobin, which makes some globules lose first their clear shape, the fixity of their form, and the faculty of being indented. Those globules adhere together, lengthen out—*en olive*—stick together, and in fulminating cases especially some are seen which are quite abnormal, while others appear quite healthy. The entire loss of elasticity of the globule (which is shown by the preservation of the elliptic form when it has been stretched out) is, in our view, a certain sign of the patient's death. To stretch out a globule you have merely to alter the inclination of a plate on which a sanguineous current has been established in the field of the microscope. The fluid column stops at one point, whereas the rest continues to flow. An elongation of the intermediary globules results, and then a rupture of the column. In the gap thus formed are some scattered globules. If these revert to their primitive form, the patient may recover. If they keep the elliptic form, we have seen death follow in every case, even if the patient's symptoms were not serious at the time of the examination of the blood."

EDUCATION in British Burmah appears to be in a sad condition. According to a correspondent of *Allen's India Mail*, the province has not yet produced any student capable of attaining the B.A. degree, and only five or six have succeeded in passing the first examination in Arts. There is no local school of medicine, and such native medicine as exists is a compound of empiricism and a belief in charms and enchantments; while the principal legal authority has repeatedly deplored the gross

ignorance of law exhibited by both advocates and judges. The Viceroy himself complained of the slowness of the official department in respect to female education. A change, however, appears to have been made by the Government of India, which has authorised the establishment of a College, though not yet of a University. Until 1881 the control of education in British Burmah was purely administrative, being vested in a Government department; but Lord Ripon decided to create a con rolling body something like the London School Board, except that its members will be nominated, not elected. The rights of the missionaries, who appear to have been the pioneers of education in the province, as well as of the Burmese themselves, were recognised, and they are represented on the new governing body. The labours of the Board so far have been very successful. It created a law school and a free library; it has organised and simplified all public examinations, and has promoted a movement amongst the wealthy natives for endowing scholarships for the higher branches of education and for the promotion of learning generally. This is all very promising; but, according to the correspondent whom we have quoted, there is a slight rift in the lute in the shape of the hostility of the local officials to the acts and even to the existence of the Board. Bureaucratic prejudice, however, can hardly hinder effectually the work of a council established on such a broad basis as this one is, backed as it also is by the authority of the Government of India.

THE Health Exhibition in connection with the Autumn Congress of the Sanitary Institute of Great Britain was opened at Dublin on Tuesday by the Lord Mayor. The inaugural address to the members of the Institute was delivered in the evening by the President, Sir Robert Rawlinson. He observed that in our own days one of the greatest works to be accomplished is to stem the torrent of sanitary ignorance now working so much mischief. Quarantine, as now practised, works at enormous money cost as well as incalculable inconvenience, and produces much misery without preventing the effects intended to be warded off. Sir Robert Rawlinson referred to the conditions under which cholera has so long afflicted India and China, partly arising from bad or insufficient food, impure water, and defective sanitary arrangements. Turning to England, he spoke of its temperate climate, pure atmosphere, and soil almost entirely free from malaria; but we have much to be ashamed of, and much to amend, in our social economy. Commenting on cholera generally, he said that occasionally it is epidemic we know. That it is contagious in the sense imagined by the ignorant experience does not prove. The President then pointed out the connection between disease and the want of good sanitary arrangements in various countries, and showed the importance of pure air, good food, pure water supply, and efficient drainage and sewerage, putting forward practical suggestions for sanitary engineers.

MAJOR SERPA PINTO, the Portuguese traveller, will leave Mozambique very shortly at the head of an expedition in order to explore the country between Mozambique and Lake Nyassa. The route to be taken is kept secret, but it is rumoured that he will proceed to the Congo, *viâ* Lake Tanganyika. The expedition, which is now being fitted out, will be on a large scale. It will comprise one hundred Inhambane Zulus as a body-guard, and two hundred and fifty carriers, and will be accompanied by a Portuguese naval lieutenant and an English photographic artist.

THE death is announced from Bangkok of Mr. Henry Alabaster, the most eminent European servant of the Siamese Government. Besides various political services, Mr. Alabaster, who had been at one time in the British Consular Service, played an important part in the great advances recently made by Siam. He introduced and established the telegraph and telephone in the country, collected a valuable European library for the palace, and originated the museum and the botanic gardens at Bangkok.

INTELLIGENCE has been received at Mozambique of the death, on August 16, of Capt. Foot, British Consul in the districts adjacent to Lake Nyassa. Capt. Foot has done some good exploring work in the Nyassa region.

THE Annual Exhibition of the Photographic Society opens at the Gallery in Pall Mall on Monday next.

A RED glow, similar to those of last year, was seen in the western sky at Berlin on September 13 at 6.45 p.m., viz. half an hour after sunset. It reached to a height of about 20° above the horizon, the colour being red to violet, which changed into a deep yellow near the horizon. Some measurements of the visible diameter was made by an observer, who discovered that the glow was limited by a spherical segment 20° in height, and with an extension towards the horizon of 35°. The centre of the segment coincided exactly with that of the sun below the horizon, which was then 78° west of the true north.

THE first news has been received from Lieut. Wissmann, leader of the expedition for the exploration of the Kasai. In a letter from Malange, dated August 25, he writes: "I am at last so far that I can say I leave this place to-morrow." Till then he had been merely making preparations.

A RECENT issue of the *Ceylon Government Gazette* contains a correspondence on the "grub" which ravages the coffee plantations of the island. The principal, and in fact only important, document in the publication is a lengthy report by Mr. R. McLachlan on the subject. Some forty species of beetles were submitted to him, but special interest centred in twenty of these, all or nearly all of which were allied to the *Melolontha vulgaris*, or common European cockchafer. Mr. McLachlan assumes that no undergrowth of grass or other herbaceous plants is allowed in the plantations, for the grubs of the European cockchafer and its allies feed on the roots of such plants, and not as a rule on those of trees and shrubs. But the larvæ would make their way from the roots of the weeds to those of the coffee plant. Whether hardening the surface of the ground around the plant so as to render it difficult for the female to deposit her eggs would be of any efficacy, is a point for the planters to decide for themselves in view of the welfare of the plant at the time. Mr. McLachlan professes himself unable to suggest any chemical poison for the grub, although he thinks that dilute kerosene oil might be tried. He advises, "above all things," to encourage insectivorous birds to the fullest possible extent, and adds that a flock of crows probably destroy more grubs in an hour than would be possible by any artificial means in a week; the systematic catching of the perfect insect or larva is also suggested as beneficial, and hand-picking should be resorted to where labour is cheap. Finally, he thinks it highly desirable that the Planters' Association or the Ceylon Government should establish an experimental plantation of a few acres, in which the natural history of the various kinds of grub, and the effect of the various supposed or real remedies, could be carefully watched.

A NEW development of telegraphy has been instituted by Michela in Italy: he has constructed a machine by which signs corresponding to various sounds can be telegraphed; thus we have practically a telegraphic shorthand to which the name "steno-telegraphy" is given. Michela's apparatus has now been in regular use for some period in telegraphing the debates of the Italian Senate. The transmitting apparatus briefly consists of two series of ten keys, each of which corresponds to some particular sound. Each key acts in reality like a Morse key, and thus transmits a current to the receiving instrument. The

receiving instrument consists of a combination of twenty Morse receivers, to each of which is attached a style which marks on the receiving paper its proper sign, thus producing a stenographic message. Great speed in transmitting is claimed for this method, and the following figures are given as comparative:—

Morse simple	500 words per hour
Hughes simple	1,200 ,, ,,
Wheatstone	1,800 ,, ,,
Steno-telegraphic	10,000 ,, ,,

A MEDICAL student, M. J. Olsen, who has been engaged during the summer in studying the fungoid flora in the neighbourhood of Bergen (Norway), has found on Ask Island a specimen of the remarkable *Tricholoma colossum*. It is the first time it has been found in Norway, and it has only once been found in Sweden. The stem is 2½ inches in diameter. Prof. Elis Fries in describing this variety says: "I discovered this unique variety for the first time among branches of spruce lying on the ground in a place near the Tem Lake in Småland (Sweden). It is the largest and finest of the hitherto discovered mushrooms."

THE thirteenth annual *conversazione* of the Chester Society of Natural Science was held in the Town Hall on September 25, and was attended not only by the members, but by a contingent of the Iron and Steel Institute, who have been holding their annual meeting in the Cestrian city. The Kingsley Memorial Medal was awarded to Mr. A. O. Walker, F.L.S., and Kingsley Memorial prizes were given for local natural history collections. It was announced that a prize of 10*l.* would be given in 1885 for the best collection of coal-measure fossil plants from the Society's district, a similar sum in 1886 for the best collection of "Bees and Wasps" from the same area, and in 1887 "for the best Essay on the Physiography of the Society's District, on the lines of Prof. Huxley's Physiography;" the district in question being Flint and Denbigh, with as much of the county of Cheshire as lies west of a line drawn south from Warrington. The exhibition of microscopic objects was, as is usually the case at Chester, exceedingly good, and for teaching purposes they were rendered more useful by the publication by the Society of a little handbook of twenty-eight pages, on Natural History, for use in the annual *conversazioni* and other meetings of the Society. It is drawn up by Mr. C. F. Fish, and appears to be an expansion of the useful programme, on which we commented last year. The information as to the classification and structures of the lower orders of life, both animal and vegetable, appear to be very carefully done, and are very concise. The work could be made much more useful by expanding the geological and physical portions: it is published at a few pence.

DR. GEORG SCHWEINFURTH has left Berlin to return to Egypt, whence he intends to start upon a new scientific exploring tour through the desert.

ON September 18 the meeting of German naturalists was opened at Magdeburg, under the presidency of Dr. Gachde. Over a thousand men of science were present. Strasburg was fixed upon as next year's meeting-place, with Profs. Kussmaul and De Bary as secretaries. Among the addresses delivered we may mention:—On the relation of micro-organisms to the infectious diseases of man, by Prof. Rosenbach (Göttingen); on the importance of German colonisation in Africa, by Dr. Gerhard Rohlfs; various medical addresses by Drs. Schwarz (Cologne), Paetz (Alt-Scherbitz), Finkler (Bonn), and Prior.

THE death is announced near Sydney of James Snowdon Calvert, the last survivor of Leichhardt's Australian exploring expedition.

A TELEPHONE now transmits, by the ordinary telegraph wire, the music from the Brussels Opera House to the Royal Châlet at Ostend. The system, of course, is Van Rysselberghe's, mentioned in our last number.

THE late Dr. Ferd. von Hochstetter's travelling reports, dating from the celebrated *Novara* Expedition (1857 59), are now being published in book form, upon the occasion of the twenty-fifth anniversary of the *Novara's* safe return to Trieste. The book will contain a portrait of the author, a preface by V. von Haardt, and a map of the course of the *Novara*. Hölzel of Vienna is the publisher.

M. CHARLES HUBER, who was travelling in the interior of Arabia in the service of the French Ministre de l'Instruction Publique (formerly together with Prof. Euting of Strasburg) has been murdered near Labegh (Rabegh?) by Bedouins of the Harl tribe. His Arabian servant Mahmoud has met the same fate.

NEWS has been received from Capt. Adrian Jacobsen, now travelling in Northern Asia, by order of the Berlin Ethnological Museum with a view of making ethnographical collections. Capt. Jacobsen, after leaving St. Petersburg, visited Kasan, Ekaterinburg, and Tomsk, and has already sent home two large cases containing ethnographical objects collected among the uncivilised Russian tribes of the Tscheremiss, and Tschmrasch, and Wotjäks.

REFERRING to our note of last week on Mr. St. Clair's "Note on a Possible Source of Error in Photographing Blood Corpuscles," the author writes to say that "in Dr. Norris's photographs where the colourless disks are well defined, the dark ones are out of focus." But it has not been shown possible to produce the ghosts while the real images are *at all* visible, and until this is done we must adhere to the opinion we have already expressed.

THE additions to the Zoological Society's Gardens during the past week include a Toque Monkey (*Macacus pileatus* ♂) from India, presented by Mrs. Batchelder; a Common Marmoset (*Hapale jacchus* ♂) from Brazil, presented by Mr. W. E. Steinscher; six Great Bats (*Vespertilio noctula*), British, presented by Mr. W. Atkinson; two King Parrakeets (*Aprosmictus scapulatus*), two Cockateels (*Calopsitta novæ-hollandiæ*) from Australia, presented by Mrs. C. Price; two Spanish Terrapins (*Clemmys trijuga*), South European, presented by Mr. W. H. J. Paterson; a Common Viper (*Vipera berus*), British, a Viperine Snake (*Tropidonotus viperinus*) from West Africa, presented by Mr. William Cross; a Common Snake (*Tropidonotus natrix*), a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain; a White-breasted Kingfisher (*Halcyon smyrnensis*) from India, two Reed Buntings (*Emberiza schœniculus*), a Blackcap (*Sylvia atricapilla*), a Pied Wagtail (*Motacilla lugubris*), British, a Tree Boa (*Corallus hortulans*) from Cuba, purchased.

OUR ASTRONOMICAL COLUMN

COMET 1884 *b* (BARNARD, JULY 16).—Dr. Berberich of Strasburg, who has investigated the elements of this comet from observations extending to September 14, has found an elliptical orbit, in which the period is only 5½ years, a result which will perhaps have been rather expected, considering the nature of the parabolic orbits previously calculated, and, as was pointed out by Prof. Weiss, their resemblance to the elements of De Vico's comet of short period observed in 1844. Dr. Berberich's ellipse is as follows:—

Perihelion passage, 1884, August 16·48346 Greenwich M.T.

Longitude of perihelion	306° 7′ 31″·1	Mean
,, ascending node ...	5 3 50·2	Equinox
Inclination	5 28 49·6	1884·0
Angle of eccentricity	36 3 43·8	
Log. semi-axis major	0·493392	
Period of revolution	2007·9 days or 5·4965 years	

At aphelion in this orbit the comet would be distant from the orbit of Jupiter 0·503, but there is a very much closer approach to the orbit of Mars, at a true anomaly of 37° 13′, corresponding to heliocentric longitude 343° 25′, where the distance of the two orbits is only 0·0088, and it is worthy of note that between April 5 and 10, 1868, both Mars and the comet would pass that point, and if Dr. Berberich's period is approximately correct, there must have been a close approach of the two bodies, possibly a closer one than calculation assigns. The following positions are deduced from the elliptical orbit:—

At Berlin, Midnight

	R.A. h. m. s.	Decl. ° ′	Log. Distance from Earth.
October 5	20 33 51	− 22 30·1	9·8331
9	20 46 54	21 2·5	9·8536
13	20 59 26	19 35·6	9·8746
17	21 11 28	18 10·0	9·8960
21	21 23 4	16 45·9	9·9175
25	21 34 14	15 23 5	9·9391
29	21 45 1	− 14 2·9	9·9608

The comet is rapidly growing fainter, but it is obviously of importance for its theory that observations should be continued as long as possible.

COMET 1884 *c*.—A new comet was discovered by Herr Wolf at Heidelberg on September 17, and was observed at Strasburg on September 20. It was also independently detected by Dr. Copeland at Dun Echt on September 22, the night before the telegraphic notice from Kiel arrived at that Observatory. Prof. Tacchini has favoured us with the following observations made by himself and Prof. Millosevich at the Observatory of the Collegio Romano in Rome:—

	Rome M.T. h. m. s.	R.A. h. m s	Decl. ° ′ ″
Sept. 21	9 24 47	21 15 46·00	+ 21 59 22·6
23	7 30 12	21 16 44·33	+ 21 7 48·7

This comet is likely to remain visible for several months, according to the orbits yet calculated, but a somewhat wider extent of observation than is now available will be required to predict its track in the heavens with any degree of certainty.

THE LUNAR ECLIPSE ON OCTOBER 4.—We gave last week the times of occultations of two stars during the totality of this eclipse, of which accurate positions are found in our catalogues. A somewhat extensive list of stars liable to occultation has been determined at Pulkowa with sufficient precision for the predictions of the times of immersion and emersion, which have been communicated to various observatories. Several stars rated higher than the ninth magnitude appear on this list, where the *Durchmusterung* magnitudes are followed. Our remark last week should have been explained as referring only to stars of which accurate places are found in the catalogues.

HYDROXYLAMINE AND THE ASSIMILATION OF NITROGEN BY PLANTS

THE researches of V. Meyer and E. Schulze on the action of hydroxylamine salts upon plants (*Berl. Ber.*, xvii. 1554) were undertaken with the *a priori* probability of showing that this base plays an important part in the synthetical activity of the plant; and although they have not succeeded in establishing the experimental fact, the results obtained are of great interest, and the whole is eminently suggestive of future possibilities. The supply of nitrogen to plants takes the form of nitrates and ammoniacal salts, and these classes of compounds being destitute of synthetical activity, we are driven to assume that the earlier stages of nitrogen assimilation consist in the conversion of these comparatively inert substances into derivatives having the "chemical tension" necessary to synthetic activity. Hydroxylamine and its salts, which occupy in point of oxidation a position intermediate between ammonia and the nitrates, are bodies possessing this character in the highest degree. To use the author's words, "the behaviour of this base towards the organic oxy-compounds is most aggressive: it is indeed astonishing with what facility it converts carbonyl-compounds into azotised derivatives." This is notably the case with the ketones and aldehydes of the fatty series, the products of the union being oximido-derivatives, *e.g.* aldoxime, acetoxime, isonitroso acids; in these the characteristic $C=NO_2$ group easily undergoes reduction, with formation of the corresponding amido derivatives; and upon the hypothesis of the formation of hydroxylamine in the plant as the first stage in nitrogen assimilation, it is easy to see in what manner its non-nitrogenous constituents, which for the most part possess the characteristics of aldehydes and ketones, would contribute to the further stages in its elaboration.

To test this hypothesis, in the first instance, the authors instituted parallel experiments on the culture of maize, to which the nitrogen was supplied in the form of ammonium sulphate, hydroxylamine sulphate, and hydrochlorate and potassium nitrate, respectively. The result was, in a word, to show that the hydroxylamine salts act as direct poisons to plant life, as indeed they have already been shown by Bertoni to act towards animal life. Having established this fact, the authors inferred their probable action as antiseptics, and experiment showed that they possess this property in a remarkable degree. This result, as they contend, does not negative the original hypothesis, as the occurrence of the base in the plant would necessarily be transitional.

It seems to us that the antiseptic properties of hydroxylamine are a direct consequence of its synthetical activity; and further that antiseptics fall into three classes according to their disturbance of one of the three essential conditions of cell life, which are: (1) hydration; (2) oxidation; (3) the synthetical activity of aldehydes (Löw and Bokorny), chiefly in the direction of condensation. In illustration of this classification we may cite as typical members of group (1) common salt, (2) sulphurous acid in its various combinations, (3) phenols.

THE BRITISH ASSOCIATION REPORTS

Second Report of the Committee, consisting of Prof. A. W. Williamson, Chairman, Profs. Sir H. E. Roscoe, Dewar, Frankland, Crum-Brown, Odling, and Armstrong, Messrs. A. Vernon-Harcourt, J. Millar Thomson, V. H. Veley, F. Japp, H. Forster Morley, and H. B. Dixon (Secretary), appointed for the purpose of drawing up a Statement of the Varieties of "Chemical Names" which have come into use, for indicating the causes which have led to their adoption, and for considering what can be done to bring about some Convergence of the Views on Chemical Nomenclature obtaining among English and Foreign Chemists.—The Report is somewhat lengthy, and includes some long tables of varieties of names for common chemical substances. It commences with historical notes on chemical nomenclature. No attempt was made until about 100 years ago to name chemical substances in a way which would indicate their composition; alchemistic or "culinary" names being given to substances in many cases. Macquer is credited with being the first to introduce generic names like vitriol and nitre to indicate sulphates and nitrates. The term salt was used to indicate almost any substance soluble in water and affecting the sense of taste, and in the eighteenth century acids, salts, and bases began to be distinguished. Rouelle was the first to define a salt from its chemical properties, and distinguish it from acids and bases (see Kopp's "History of Chemistry," iii.). Bergmann and Guyton de Mouveau separately proposed systems of nomenclature, many terms of which are still in use. De Mouveau made the terminations of names of acids uniform, and the names of salts to indicate their composition from bases and acids. In 1787 Lavoisier, De Mouveau, Berthollet, and Fourcroy prepared a scheme of naming compounds which is practically that in common use now, introducing the terminations "ate" and "ic," "ite" and "ous," in acids and salts. But higher and lower oxides are not distinguished by generic names. Berzelius made a more elaborate classification of salts, and added some names. He distinguished the halogen compounds of hydrogen as hydracids, and distinguished clearly between "neutral," "acid," and "basic" salts. The views now held of acids, salts, and bases are practically those of Gerhardt and Laurent, who first recognised the part played by hydrogen in acids and salts. The Report then goes on to consider the tables, which give the number of times a substance has been distinguished by any particular name. Table I. deals with the names of oxides of carbon from 1755 to 1882. By far the greater number of sources give the names carbonic oxide to CO and carbonic acid to CO_2; systematic names like carbonous oxide and carbonic oxide only occurring two or three times, the terms carbonic oxide and carbonic anhydride or dioxide being next in frequency. In France and Germany the names oxide de carbon and acide carbonique, Kohlenoxyd and Kohlensäure have been much more frequently used. But in several instances the same names have been used in a different sense; the term carbonic oxide being some-

times used for CO_2, sometimes for CO. In Table II. the prominence of this "diversity of names for the one thing," and giving the same name to distinct substances, is more frequent. The use of numerical prefixes has also been very irregular; "thus, trisodic phosphate has been called 'triphosphate of soda,' 'diphosphate of soda,' and 'sesquiphosphate of soda'; in all these cases the prefix is intended to indicate the number of molecules of soda to one molecule of phosphoric acid." "In some of the older forms of nomenclature ambiguity was avoided by using the prefix 'bi-' to multiply the acid when in excess over the base, and 'di-' to multiply the base when in excess over the acid; thus, Na_2O2SiO_2, bisilicate of soda, $2Na_2OSiO_2$, disilicate of soda." The Report goes on to say that "the usefulness of any system of nomenclature depends on its permanence." Curiously enough the tables show that where names have been adopted supposed to represent in some way the chemical constitution of bodies, they have not, as a rule, endured; the advance of knowledge necessitating a change of opinion, whilst names not expressing a chemical opinion as to constitution have endured. "As a rule, those names are to be preferred which have shown most vitality and have led to no ambiguity. Where there are two compounds composed of the same elements, the terminations 'ous' and 'ic' should be employed. The prefixes 'proto' and 'deuto,' introduced by Thomas Thomson, were intended to mark the compounds in a series, not the number of atoms in a molecule. Where retained this use only should be made of them." Referring to change of name, instance is made of the oxides of carbon, the names of which have recently to some extent been transposed, the higher one being termed "carbonic oxide," and the lower one, to which the term "carbonic oxide" has long been applied, has had a new name. The sensible conclusion of the Report is to retain names of substances which are in common use, rather than to change them for names indicating constitution, and which might be again found to require alteration in accordance with some new view of the constitution of the substance.

SECTION B—CHEMISTRY

At the meeting of the Chemical Section at Montreal a new departure was made in the selection by the Organising Committee of two subjects for special discussion. The subjects chosen were: "The Constitution of the Elements," and "Chemical Changes in their Relation to Micro-Organisms."

Discussion on "The Constitution of the Elements"

Prof. Dewar began by referring to Grove's discovery that water suffered decomposition at the temperature of the oxy-hydrogen flame, an experiment which led Sainte-Claire Deville to undertake his researches on dissociation. Deville has shown that in compound substances there is an equilibrium between decomposition and recomposition, this balanced relation changing with the temperature. The experiments of Deville on the temperature of burning gases agree closely with the results obtained by Bunsen, who determined the pressures generated in the explosion of hydrogen and other gases with oxygen. The breaking up of the iodine molecule, effected by Victor Meyer, is a decomposition of elementary matter. Owing to the rapid recomposition, there seems no hope of isolating atomic iodine at low temperatures. The vapours of potassium and sodium have different densities at different temperatures; probably also their molecules consist of two atoms at lower, and of one atom at higher, temperatures. More exact determinations are needed of those substances which exhibit a variable vapour density. The evidence afforded by spectral analysis proves that oxygen and nitrogen have two spectra, and therefore probably different molecules at different temperatures. Hydrogen has a complicated spectrum under certain conditions. Referring to Mr. Lockyer's speculations, he said there was a general basis of similarity in the type of the vibrations of certain allied elements, viz. the triple lines in zinc and cadmium. Mr. Lockyer has proved that the identity of certain "basic" lines of different elements, such as iron and calcium, is not due to impurity, but the greater dispersion of more powerful instruments has shown that the coincidence of these lines is only apparent and not absolute. The differences observed in some of the spectral lines of a single element in the sun might be accounted for not by the decomposition of the "element" into simpler matter but by great differences of level in the luminous vapour. Prout's hypothesis, that the atomic weights of the other elements are multiples of that of hydrogen, has no basis in experimental fact. Stas and Marignac have both returned in their old age to the redetermination of the atomic weights made by them twenty years ago. Stas, avoiding the possible sources of error in his former methods, has lately found 14·055 for the atomic weight of nitrogen; his old determinations gave 14·044. For potassium he now arrives at the number 39·142 instead of 39·137. Marignac gives the following as the atomic weights of zinc and magnesium, 65·33 and 24·37,—numbers very far removed from whole numbers.

Prof. Wolcott Gibbs drew the attention of the Section to the probability that what is generally regarded as a simple molecule, such as sodium chloride, consists in the solid state of several hundreds of atoms, and that the salt undergoes in solution a kind of molecular dissociation. Very complex molecules, such as those acids he had prepared containing many molecules of the oxides of molybdenum, vanadium, barium, &c., are probably derived by substitution from what are called simple molecules, but which are really composed of a great number of atoms.

Prof. Frankland said he ventured to differ from Prof. Dewar in one point. He thought it might not be impossible by a decomposition of compound molecules to prepare isolated iodine atoms.

Sir Lyon Playfair suggested as a useful line of work the determination of the conditions under which such bodies as nitric peroxide would enter into combination with other compounds.

Prof. Tilden pointed out that a large field lay open to workers in thermo-chemistry, on the one hand in determining the temperatures at which chemical action begins, and on the other the heat-changes of chemical combination and solution at different temperatures.

Rev. Father Perry agreed with Prof. Dewar that some differences in the solar lines were due to difference of level of the luminous vapour. But, on the other hand, the widening of solar lines in the umbra of spots cannot be accounted for in this way. The Astronomer-Royal and Mr. Lockyer have been studying the solar spectrum from the line D to F. The Rev. Father Perry (studying D towards B) has found differences in the lines of the same metal in different spots which could not be attributed to difference of level only.

Prof. Dewar, in answer to Father Perry, stated that the widening of certain lines at the red end of the spectrum might have been anticipated from the results of his own work in the crucible. The supposed allotropic spectrum of magnesium is due to a compound of magnesium and hydrogen. The fact that in the upper regions of the solar atmosphere, where hydrogen and magnesium occur in enormous quantities, this allotropic spectrum is not observed presents a difficulty. Perhaps at the mean temperature of the solar atmosphere this compound is dissociated. If so, somewhere nearer the surface or in the spots a condition of temperature should occur in which the compound should be stable. He hoped Father Perry would succeed in observing this spectrum in the umbra of spots. It had been stated that if our elements are compound substances they should be found decomposed at the enormously high temperatures of the sun; but if it is admitted that the elements are compounded of hydrogen, and that dissociation can occur, the compound vapour is diffused through an atmosphere of hydrogen, one of the products of its dissociation, and is therefore precisely under those conditions in which it is most stable.

Discussion on "Chemical Changes in their Relation to Micro-Organisms"

Prof. Frankland, in opening the discussion, distinguished between two kinds of chemical action—(1) that in which substances brought into contact mutually undergo chemical change, and (2) that in which chemical change is effected in one substance by contact with another, which itself apparently suffers no alteration. The following definitions were proposed to distinguish animal and vegetable organisms:—(1) A plant is an organism performing synthetical functions, or one in which these functions greatly predominate; it transforms actual into potential energy. (2) An animal is an organism performing analytical functions, or one in which these functions greatly predominate; it transforms potential into actual energy. All micro-organisms appear to belong to the second class. Oxidation is the essential condition of life. There are, however, many other chemical transformations in which potential becomes actual energy, and which therefore can support life. After de-

scribing the chemical changes produced by a large number of micro-organisms, the author concluded that there is no break in the continuity of chemical functions between micro-organisms and the higher forms of animal life. It is true there are apparently certain sharp distinctions between them. The enormous fecundity of micro-organisms and their tremendous appetites seem to separate them from the higher orders of animals. But this distinction is only comparative. It must be borne in mind that an animal like a sheep converts much of its food into carbonic acid, hippuric acid, and water, thus utilising nearly the whole of the potential energy, while the micro-organism as a rule utilises only a small portion. Those micro-organisms which have been chemically studied produce, like the higher animals, perfectly definite chemical changes. The position of these organisms in Nature is only just beginning to be appreciated. It may safely be predicted that there is no danger of their being spoiled by the petting of sentimentalists, yet these lowly organisms will receive much more attention in the future than they have done in the past.

Principal Dallinger referred to the attempted distinction between the lower animal and vegetable forms. In following out the life-history of certain monads he used a nutritive fluid containing no albuminoid substances, but only mineral salts and tartrate of ammonium. Organisms classed by Prof. Huxley as animal were found to live in this mineral fluid. Bacteria of forms which cannot be distinguished by the microscope have very different physiological functions. These Bacteria can be modified physiologically, but not at all readily morphologically; by a slow change it is possible to completely reverse the conditions of the environment of the Bacterium without changing its form. It is most important to study the physiology of Bacteria.

Dr. Macalister pointed out that the experiments made on the conversion of the Bacillus of the hay infusion into the *Bacillus anthracis* had not been confirmed by more exact experiments. The germs of the *Bacillus anthracis* readily diffused themselves through the air of the laboratory, and without the very greatest care it was impossible to avoid contamination of the liquids with stray germs.

Prof. Dewar referred to the extraordinary behaviour of very small quantities of peroxide of hydrogen on putrescible liquids. One-hundredth of a per cent. of the peroxide perfectly preserved many liquids, keeping them quite clear and without a trace of any Bacteria. The conversion of sugar into anhydrous alcohol and carbonic acid seemed to be unaccompanied by a thermal change, so that an important question arises, Where does the power which effects the change come from? Possibly, like chlorophyll, the Bacteria absorb rays of radiant heat and light. Dr. Engelman has studied the distribution of radiant energy in the spectrum of the sun and flames by the activity of the Bacteria submitted to different parts of the spectrum.

Sir Lyon Playfair regarded it as curious that the products formed in the growth of the higher animals—namely, carbonic acid and urea—should be so much simpler than the products formed by lower organisms.

Complex Inorganic Acids, by Prof. Wolcott Gibbs.—This research may be regarded as a series of generalisations of the class of silico-tungstates discovered by Marignac in 1861, and of the analogous class of phospho-molybdates studied by Deville. Scheibler has described two distinct series of phospho-tungstates; the author finds there are at least ten, the highest having the formula $24WO_3,P_2O_5,6H_2O$, the lowest the formula $6WO_3,P_2O5,6H_2O$, and that the phospho-molybdates are at least equally numerous, and have a similar range. Corresponding compounds containing arsenic oxide also exist. To generalise these results the author replaced phosphoric oxide by vanadic oxide and antimonic oxide, so as to form vanadio-tungstates and antimonio-tungstates, and the corresponding compounds of molybdenum. Many of these salts are very beautiful. Probably the greater number of oxides of the type R_2O_5 form similar compounds. A second series of complex acids contain *two* molecules of the type R_2O_5, so that we have various phospho-vanadio-tungstates and phospho-vanadio-molybdates. The generalisation of the term WO_3 or MoO_3 appears also possible, as the author has prepared compounds in which sulphur and selenium replace oxygen in WO_3 or MoO_3. Again, the author finds that phosphorous and hypophosphorous acids enter into similar combinations with tungstic and molybdic acids, and he has also prepared compounds in which the methyl, ethyl, and phenyl derivatives of phosphorous and hypophosphorous acids occur. An attempt to prepare complex acids containing pyro-phosphoric acid failed, as that acid quickly changed to the ortho-acid; but with metaphosphoric acid the author succeeded in preparing several new compounds. The author has further shown that the group R_2O_5 may be replaced by R''_2O_3, $R'''Cl_2$—R'' being a metal of the platinum group—and that the chlorine can be replaced by bromine or iodine. The type of silico-tungstates is also capable of generalisation, silica being replaced by a large number of similar oxides, as, for instance, the oxides of selenium, tellurium, platinum, &c. As an instance of the extreme complexity of some of these compound acids, the author gave the body $60WO_3,3P_2O_5,V_2O_5,VO_2,18BaO,+150Ag$. This body has the enormous molecular weight of 20,066. In conclusion the author stated that in formulating certain compounds containing V_2O_5 he found much similar expressions resulted when a part of the V_2O_5 was supposed to have the structure $(V_2O_2)O_3$, (V_2O_2) replacing W or Mo.

On the Incomplete Combustion of Gases, by H. B. Dixon.—The author gave a *résumé* of the work he had done in continuation of the researches of Bunsen, E. von Meyer, Horstmann, and other chemists, on the division of oxygen when exploded with excess of hydrogen and carbonic oxide. The following are the general conclusions arrived at:—(1) No alteration *per saltum* occurs in the ratio of the products of combustion. The experiments made completely confirm Horstmann's conclusion: Bunsen's earlier experiments are vitiated by the presence of aqueous vapour in the eudiometer. (2) A dry mixture of carbonic oxide and oxygen does not explode when an electric spark is passed through it. The union of carbonic oxygen is effected indirectly by steam. A mere trace of steam renders the admixture of carbonic oxide and oxygen explosive. The steam undergoes a series of alternate reductions and oxidations acting as a "carrier of oxygen" to the carbonic oxide. With a very small quantity of steam the oxidation of carbonic oxide takes place slowly; as the quantity of steam is increased the rapidity of explosion increases. (3) When a mixture of dry carbonic oxide and hydrogen is exploded with a quantity of oxygen insufficient for complete combustion, the ratio of the carbonic acid to the steam formed depends upon the shape of the vessel and the pressure under which the gases are fired. By continually increasing the initial pressure a point is reached where no further increase in the pressure affects the products of the reaction. At and above this critical pressure the result was found to be independent of the length of the column of gases exploded. The larger the quantity of oxygen used, the lower the "critical pressure" was found to be. (4) When dry mixtures of carbonic oxide and hydrogen in varying proportions are exploded above their critical pressures with oxygen insufficient for complete combustion, an equilibrium is established between two opposite chemical changes represented by the equations:—

$$\text{(I.)}\ CO + H_2O = CO_2 + H_2.$$
$$\text{(II.)}\ CO_2 + H_2 = CO + H_2O.$$

At the end of the reaction the product of the carbonic oxide and steam molecules is equal to the product of the carbonic acid and hydrogen molecules multiplied by a coefficient of affinity. This result agrees with Horstmann's conclusion. But Horstmann considers the coefficient to vary with the relative mass of oxygen taken. (5) A small difference in the initial temperature at which the gases are fired makes a considerable difference in the products of the reaction. This difference is due to the condensation of steam by the sides of the vessel during the explosion, and its consequent removal from the sphere of action during the chemical change. When the gases are exploded at an initial temperature, sufficiently high to prevent any condensation of steam during the progress of the reaction, the coefficient of affinity is found to be constant whatever the quantity of oxygen used—provided only the quantity of hydrogen is more than double the quantity of oxygen. (6) The presence of an inert gas, such as nitrogen, by diminishing the intensity of the reaction, favours the formation of carbonic acid in preference to steam. When the hydrogen taken is less than double the oxygen, the excess of oxygen cannot react with any of the three other gases present—carbonic oxide, carbonic acid, and steam, but has to wait until an equal volume of steam is reduced to hydrogen by the carbonic oxide. The excess of inert oxygen has the same effect as inert nitrogen in favouring the formation of carbonic acid. The variations in the coefficient of affinity found by Horstmann with different quantities of oxygen are due partly to this cause, but chiefly to the varying amounts of steam condensed by the cold eudiometer during the reaction in different experiments. (7) As a general

result of these experiments it is shown that, when a mixture of dry carbonic oxide and hydrogen is exploded with oxygen insufficient for complete combustion, at a temperature at which no condensation of steam can take place during the reaction, and at a temperature greater than the critical pressure, an equilibrium between two opposite chemical changes is established which is independent of the mass of oxygen taken, so long as this quantity is less than half the hydrogen. Within these limits the law of mass is completely verified for the gaseous system composed of carbonic oxide, carbonic acid, hydrogen, and steam at a high temperature.

On Magnetic Rotation of Compounds in Relation to their Chemical Composition, by W. H. Perkin, Ph.D., F.R.S.—The author gave a *résumé* of his researches on the magnetic rotary polarisation of compounds in relation to their chemical composition. After referring to the remarkable discovery of Faraday in relation to this subject, and the results obtained by more recent workers in this field, it was shown that no relationship in reference to chemical composition was likely to be found by the usual method of calculating the results of the observation of unit-lengths of the fluid bodies examined, but that, if lengths related to each other in proportion to their molecular weights—making the necessary correction for the difference of densities—were compared, a useful result would probably be obtained. Experiments have proved this to be the case; and in the series of homologous compounds it was found that for every addition of CH_2 a definite increase of what is called the "molecular rotation" is obtained. Besides this it was found that the rotation also was capable of indicating differences in the construction of organic compounds. Iso, secondary, tertiary bodies give different results from the normal compounds. The compounds containing the halogens were also referred to, and formulæ given by which the molecular rotation of twenty-six series of compounds could be calculated.

Spectroscopic Studies of Explosions, by Profs. Liveing and Dewar.—The explosions observed were chiefly those of hydrogen and oxygen and of carbonic oxide and oxygen, and were made in an iron tube fitted with quartz ends. The spectra were both observed with the eye and photographed. Linings of thin sheet metal of various kinds were introduced into the tube. The metals iron, nickel, and cobalt gave many lines in the flash. No other metal gave anything like so many lines as these three, but magnesium gave the *b* group, copper gave one green and two ultra-violet lines, manganese the violet triplet, and chromium three triplets. On the other hand, zinc, cadmium, mercury, aluminium, bismuth, antimony, and arsenic developed no lines in the flash. It appears to be proved that iron, nickel, and cobalt are volatile in some degree at 3000°. It might be possible to establish a spectroscopic scale of temperature if the lines successively developed with increasing temperature were noted. Thus, the iron line T seems to be just developed at 3000°, the aluminium lines at H at a somewhat higher temperature, the lithium blue line may be just seen in the inner green cone of a Bunsen burner, while the green line comes out in the explosion fla h. [The photographs of the explosion spectra were exhibited to the Section.]

On Evaporation and Dissociation, by Prof. William Ramsay and S. Young, D.Sc.—The authors described experiments made with the object of ascertaining whether the coincidence of the curves which represent the vapour-pressures of stable solid and liquid substances at different temperatures with those indicating the maximum temperatures attainable by the same substances at different pressures, when evaporating with a free surface, holds good also for substances which dissociate in their passage to the gaseous state. The substances examined were chloral hydrate, ammonium carbamate, phthalic acid, succinic acid, aldehyde ammonia, ammonium chloride, nitric peroxide, and acetic acid. It was found that, with chloral hydrate and ammonium carbamate, which cannot exist at all in the gaseous state, the temperatures of volatilisation do not form a curve. When the dissociation was considerable, but not complete, as in the case of phthalic and succinic acids, an indication of a curve was observed at low pressures, but it differed widely both in form and position from that representing the vapour-pressures or pressures of dissociation. As the dissociation increases the curves approach each other more closely, and they appear to be coincident in the case of ammonium chloride and nitric peroxide within the limits of temperature at which observations were made, and at which the amount of dissociation is probably small. With acetic acid very numerous observations proved the perfect coincidence of the curves. The results appear to be unfavourable to the view that, when liquefaction of a stable substance takes place, gaseous molecules coalesce to form more complex groups of molecules, and that these complex molecules dissociate when the substance is vaporised.

A Redetermination of the Atomic Weight of Cerium, by H. Robinson, B.A. Cambridge.—Cerous chloride was prepared by passing hydrochloric acid over cerium oxalate at first gently heated and afterwards raised to redness. The solution of pure chloride was added to a pure solution of silver nitrate, and then dilute solution of silver nitrate was added from a weighed bulb, until the precipitation of chlorine was complete. The liquids were illuminated by yellow light only during the precipitation. As a mean of seven closely concordant results, the atomic weight of cerium is given as 140·2593, that of silver being 107·93.

The Action of Sulphuretted Hydrogen on Silver, by Prof. F. P. Dunnington, University of Virginia.—A piece of pure silver, flattened and carefully polished on each face, was placed in the middle of a glass tube two feet long. At each end of the tube a plug of five inches of phosphoric anhydride was confined by glass wool. Pure dry hydrogen was passed through this tube while it was gently heated throughout. The hydrogen was then removed by a Sprengel pump, the silver being heated to 3.0° C. This operation was repeated three times, and then pure dry sulphuretted hydrogen was slowly passed through the apparatus for an hour, and the tube finally drawn off at each end. After a few days the silver was slightly darkened near its edges, and after five months the silver was blackened on its edges, while the main portion of the surface was white and bright. [The silver was exhibited to the Section in this state.]

On Molecular Volumes, by Prof. W. Ramsay.—The object of this research was to ascertain whether, as has long been taken for granted, the boiling-point of compounds under equal pressures really afforded suitable points for a comparison of their molecular volumes. The experiments made with the following series of compounds—water, methyl alcohol, ethyl alcohol, propyl alcohol, isopropyl alcohol, isobutyl alcohol, and ether—prove that the value of the group CH_2 is by no means constant. (1) While at the boiling-points of these liquids at low pressures the value is approximately constant (fluctuating between 17·5 and 22), at high temperatures the difference becomes much more marked, attaining at 20 m. of mercury pressure the greatest irregularity; *e.g.* the difference between the molecular volumes of ether and isobutyl alcohol, two isomeric substances, amounts to a total of twenty units. (2) It was found by experiment that when the liquids were at temperatures corresponding to equal vapour-pressure, but exposed to their critical pressures, no correspondence between their molecular volumes was observable. (3) It was thought possible that if the liquids, still at temperatures corresponding to equal vapour-pressure, could have existed under no pressure, some basis of comparison might be found. From the known compressibility of the liquids it was possible to calculate their volume in this hypothetical state. Although by this method their relative volumes were considerably altered, yet no point of co nparison was reached. (4) The author therefore concludes that the boiling-points of liquids, under whatever pressure they may be taken, are not suitable temperatures at which to compare their molecular volumes.

On Some Phenomena of Solution, Illustrated by the Case of Sodium Sulphate, by Prof. W. A. Tilden, F.R.S.—The study of the solubility of sodium sulphate in water at temperatures above 100° C., leads to the conclusion that the salt dissolves in the anhydrous state. In order to determine whether this salt dissolves in water at lower temperatures in the anhydrous or the hydrated state, the author has made a series of calorimetric measurements of the thermal changes which attend the act of solution of Na_2SO_4 in water at temperatures below and above 33° to 34°, the critical point in the curve of solubility.

Calorimetric Effect of Dissolving Na_2So_4 in n *Molecules of Water at T°*

n	T°	C
100	31·7	1740
100	35·4	1522
100	42·85	1342
100	46·1	1071
100	55·0	985

These figures establish the fact that by dissolving anhydrous sodium sulphate in water at temperatures above 33°, the thermal change is still positive, although a diminishing quantity, and

hence that the act of solution is still attended at these temperatures by chemical combination between the salt and the water. These results when plotted out give a line which is nearly parallel to the curve of solubility between these limits of temperature.

On Calcium Sulphide and Sulpho-carbonate, by V. H. Veley, M.A.—Calcium oxide, free from metals of the iron group, was obtained by heating perfectly transparent crystals of Iceland spar in a current of hydrogen. This oxide was hydrated in a damp atmosphere free from carbonic acid. The hydroxide was heated to 60° C., and hydric sulphide passed over it. The resulting calcium sulphide and water were weighed, and the synthetic results thus obtained were found to agree closely with the results of the analysis of the calcium sulphide. It is worthy of note that perfectly dry calcium oxide is unaltered by the passage over it of perfectly dry hydric sulphide, and generally the formation of calcium sulphide proceeded the more rapidly the greater the quantity of water originally present in the hydroxide. This result may be due to the formation, at first, either of the hydrosulphide, or the hydroxy-hydrosulphide (CaOH,SH), and the subsequent conversion of either of these substances into the sulphide. The calcium sulphide, prepared as described above, was moistened with water, and hydrogen saturated with carbon bisulphide passed through it. It gradually turned yellow, and finally red, and on exhaustion with cold water a red solution was obtained, from which, on evaporation *in vacuo*, red, deliquescent, prismatic crystals separated. The composition of these crystals was found by analysis to correspond with the formula $Ca(OH)_2,CaCS_3xH_2O$. A solution of this substance gave characteristic precipitates with metallic salts, which the author intends to examine more minutely.

On the Velocity of Explosions in Gases, by H. B. Dixon, M.A.—MM. Berthelot and Vieille have shown that in oxygen and hydrogen and several other mixtures of gases the "explosive wave" is propagated at a velocity closely approximating to the mean velocity of translation of the gaseous products of combustion calculated on the assumption that all the heat of the reaction is contained for the moment in the products formed. The mean of a number of determinations with electrolytic gas gave a velocity of 2810 m. per second, the calculated mean velocity of the steam molecule formed being 2831 m. per second. These experimenters found that carbonic oxide exploded either with oxygen or nitrous oxide did not agree with the rule. The author has shown that steam is necessary for the burning of carbonic oxide both with oxygen and nitrous oxide, and that, as the proportion of steam is increased, the rate of inflammation is also increased. Experiments made in a lead tube 55 m. long and 13 mm. in diameter entirely confirmed MM. Berthelot and Vieille's experiments with hydrogen and oxygen. The rate of the "explosive wave" was found to be 2817 m. per second as the mean of several closely concordant experiments at 10° C. With carbonic oxide and hydrogen nearly dry, the explosive wave was not established until the flame had traversed a distance of 700 mm. from the firing-point: the explosive wave was found to have a velocity rather over 1500 m. per second. After the explosion a fine layer of carbon was found to cover the inside of the explosion-tube, showing that at the enormous temperature of the explosive wave carbonic oxide is decomposed into its constituents.

A Theory of Solution, by W. W. J. Nicol, M.A., B.Sc.—The author has proposed the theory that the solution of a salt in water is a consequence of the attraction of the molecules of water for a molecule of salt exceeding the attraction of the molecules of salt for one another. It follows, therefore, that, as the number of dissolved salt molecules increases, the attraction of the dissimilar molecules is more and more balanced by the attraction of the similar molecules: when these two forces are in equilibrium, saturation takes place. Any external cause tending to alter the intensity of either of these two opposite forces disturbs the condition of equilibrium, and further solution or solidification ensues. The contraction which occurs on the solution of a salt in water has been regarded as strong evidence in favour of chemical combination having taken place, but the author finds that a further contraction takes place on further dilution, even when the number of water molecules per salt molecule is far in excess of the number in the cryohydrates.

On the Manufacture of Soda and Chlorine, by W. Weldon, F.R.S.—Chlorine is at present manufactured exclusively from hydrochloric acid, obtained as a by-product of the manufacture of soda by the Leblanc process. It is owing to this that the Leblanc process has been able to withstand the severe competition of the ammonia process, which gives soda much more cheaply than the Leblanc process, but does not yield either hydrochloric acid or chlorine. The author announces a process for the preparation of chlorine in connection with the manufacture of soda by the ammonia process. The new process consists in decomposing by magnesia the ammonium chloride of the ammonia-soda process, adding magnesia to the resulting solution of magnesium chloride, and so obtaining solid oxychloride of magnesium, which, heated in a current of air, gives off chlorine and leaves magnesia.

On the Diamond-bearing Rocks of South Africa, by Prof. Sir Henry E. Roscoe, President.—After an introductory description of the geological and physical aspects of the remarkable diamond-bearing deposits at Kimberley and elsewhere, the author gave the chemical composition of these rocks. The most noteworthy feature of the examination of these rocks is the discovery in the so-called diamond earth of a volatile crystalline hydrocarbon, soluble in ether, which seems to confirm the hypothesis that the Carboniferous shales, which are penetrated by the diamond-bearing pipes, have been the source of the carbon now found in the crystalline state in the diamond. The physical structure of the ash or incombustible portion of the diamond is of a very singular character, and has hitherto not been examined. A careful study of the diamond ash may possibly throw light on the important question of the mode of formation of the diamond.

Colour of Chemical Compounds, by Prof. Carnelley, D.Sc. —The colour of chemical compounds is conditioned by at least three circumstances, viz. (1) temperature (Ackroyd); (2) the quantity of the electro-negative element present in a binary compound (Ackroyd); (3) the atomic weights of the constituent elements of the compounds (Carnelley); and that in such a way that the colour passes or tends to pass through the following chromatic scale—white or colourless, violet, indigo, blue, green, yellow, orange, red, brown, black—either by (1) rise of temperature, or (2) increase of the quantity of the electro-negative element in a binary compound, or (3) with *increase* of the *atomic weights* of the elements A, B, C, &c., in the compounds A_xR_y, B_xR_y, C_xR_y, &c., in which R is any element or group of elements, whilst A, B, C, &c., are elements belonging to the same sub-group of Mendeléeff's classification of the elements. Tables accompany the paper in illustration of the above. Out of 426 cases in which the third of the above rules has been applied, there are but sixteen exceptions, or less than 4 per cent. Finally a theoretical explanation is given which appears to account in a very simple manner for the influence of the above three circumstances on the colour of chemical compounds.

Notes of Nitrification, by R. Warington.—He considered the present position of the theory of nitrification, and next gave a short account of the results of recent experiments conducted by him at Rothamsted. Messrs. Schloesing and Müntz, early in 1877, showed that nitrification in sewage and in soils is the result of the action of an organised ferment, occurring in soils and impure waters. The experiments of the author have confirmed the soundness of this theory. The evidence for the ferment theory is now very complete. Nitrification in soils and waters is strictly limited to range of temperature within which the vital activity of the living ferment is confined. It proceeds with slowness at 0°, is at a maximum at 37°, and ceases at 55°. Nitrification is also dependent on plant food suitable for organisms of low character. Further proof of the ferment theory is that antiseptics are fatal to nitrification. Heating sewage to boiling-point, or soil to the same temperature, effectually prevents it. Finally, nitrification can be started in boiled sewage or other sterilised liquid by the addition of a little surface soil or a few drops of a solution already nitrified. These nitrifying organisms have as yet received but little microscopical study.

On the Liquefaction of Oxygen and the Density of Liquid Hydrogen, by Prof. Dewar, F.R.S.—The problem of liquefying oxygen and hydrogen, and consequently others of the so-called permanent gases, having been solved by Cailletet and Pictet, the author has since been employed studying the physical characters of these gases in the condensed state. The critical pressures and temperatures at condensation have been determined, and the relation of one to the other is shown to be constant. The merits of various cold producers that could be employed in the process were discussed. Condensed ethylene he considered the best, then condensed nitrous oxide and carbonic acid. The lowest temperature that could be obtained by carbonic acid is about 115° C., and by nitrous oxide 125° C.

On the Production of Permanent Gas from Paraffin Oils, by

Dr. Stephen Macadam.—For the last fourteen years the author has devoted much attention to the illuminating values of different qualities of paraffin oils in various lamps, and to the production of permanent illuminating gas from paraffin oils. The earlier experiments were directed to the employment of paraffin oils as oils, and the results proved the superiority of the paraffin oils over vegetable and animal oils, especially for lighthouse service. The later trials were mainly concerned with the breaking up of the paraffin oils into permanent illuminating gas, and the results formed the basis on which paraffin oil gas has been introduced into the lighthouse service of Great Britain, both for illuminating purposes and as fuel for driving engines of fog-horns. The following table shows the results of his investigations on the relative values of the crude, green, and blue oils:—

	Crude	Green	Blu
Gas per gallon in cubic feet ...	98 ...	102 ...	127
Candle power	50 ...	53 ...	54
Light value of gas from ton of oil given in lbs. of sperm candles	4494 ...	4741 ...	6044

On the Assimilation of Atmospheric Nitrogen by Plants, by W. O. Atwater.—It is almost a universal opinion that free nitrogen is not assimilated by plants. He referred to the classic experiments of Boussingault and Lawes, of Gilbert and Pugh, which, commonly regarded as decisive, may have been performed without consideration to certain conditions. Experiments made by the author show that at any rate certain plants grown under normal conditions do assimilate nitrogen. Peas were grown in sand which had been purified by burning and washing, and to which were applied nutritive solutions containing known quantities of nitrogen. The amount of nitrogen supplied to the plant plus the amount contained in the seed was compared after the experiment with the amount given by analysis of the plant and the residual solution. The excess of the latter amount over the former, which in some cases was excessive, represented the nitrogen acquired from the air.

Prof. Gilbert dissented from the conclusion drawn by Prof. Atwater, as he had found that, the greater the care used to prevent foreign matters accumulating on the plants under experiment, the less nitrogen was found in excess of that obtained from the seed and soil.

Prof. Frankland communicated the results of a study of the phenomena attending the discharge of accumulator-cells containing alternate plates of lead peroxide and spongy lead: (1) The energy of a charged storage-cell is delivered in two separate portions, one having an E.M.F. of 2 volts and upwards, the other an E.M.F. of 0·5 volt and under. One of these may be conveniently termed *useful*, and the other *useless*, electricity. (2) The proportion of useful electricity obtainable is greatest when the cell is discharged intermittently, and least when the discharge is continuous. (3) Neither in the intermittent nor continuous discharge at high E.M.F. is the current, through uniform resistance, augmented by rest. At low E.M.F., however, the current, after continuous discharge of the high E.M.F. portion, is greatly augmented, but only for a few minutes. This augmentation of current at low E.M.F. after rest is hardly perceptible when the high E.M.F. discharge has been taken intermittently. (4) The suddenness of fall in potential indicates two entirely distinct chemical changes, the one resulting in an E.M.F. of about 2·5 volts, the other in one of about 0·3 volt. (5) The chemical change producing low electromotive force is the first to occur in charging, and the last to take place in discharging, the cell. It is the change which occurs during what is called the "formation" of a cell, and, for economy's sake, a reversal of this change should never be allowed to take place. (6) Currents of enormous strength can be readily obtained from storage batteries coupled up in parallel, viz. a current of 25,000 amperes from only 100 cells. Such a current reduces to insignificance the output of the largest dynamo ever built. It is to be hoped that currents of this magnitude will open up new probabilities of research into the constitution of matter.

SECTION C—Geology

Plan for the Subject-Bibliography of North American Geology, by G. K. Gilbert, of the U.S. Geological Survey.—The United States Geological Survey is engaged on a Bibliography of North American Geology. The work when completed will give the title of each paper with the title-page of the containing book, and the number of plates, the whole being arranged alphabetically by authors. There is in contemplation also the simultaneous preparation of a number of more restricted bibliographies, each covering a division of geologic literature. The plan includes abbreviated titles of papers with reference to the pages on which the special subjects are treated, the entries in each bibliography being arranged alphabetically by authors. The selection of topics for treatment in this manner involves the classification of geologic science, and Mr. Gilbert submitted a tentative classification requesting the criticism of geologists.

Marginal Kames, by H. Carvill Lewis, A.M., Professor of Geology at Haverford College.—After reviewing the work on American kames, and the theories of the origin of kames, the author describes his investigations of short kames at the extreme margin of the ice-sheet along the line of the terminal moraine in Pennsylvania. These *marginal kames* run *backwards* from the edge of the ice, draining it by a sub-glacial drainage. These kames are discussed in detail, and are thought to represent sub-glacial rivers formed during the melting of the ice-sheet.

On the Geology of South Africa, by T. Rupert Jones, F.R.S., F.G.S., &c.—The contour of the south coast is parallel with the outcrop of the strata in the interior, from Oliphant's River (31° 40′ S. lat.) on the west coast, southward to the Cape, and then eastward to about 33° 30′ S. lat. Here the edges of the strata, formerly bending round to the north, have been swept away to a great extent; but their outcrop is again seen on the east coast at St. John's River (31° 40′ S. lat.), where they strike north-eastwardly through Natal, probably far up the country. (1) Gneissic rock and the Namaqualand Schists apparently underlie the others, coming out on the north west, and exposing a narrow strip on the south coast. (2) Mica Schists and Slates, interrupted by Granites here and there, form a curved maritime band, from about 30 to 70 miles broad, and are known as the Malmesbury Beds (Dunn). These and the beds next in succession (the Bokkeveld Beds, 3) are overlain unconformably by the Table-Mountain Sandstone (4), 4000 (?) feet thick, which forms patches and extensive ridges, and possibly dips over No. 3, to join No. 5, the Witteberg Beds. Nos. 3 and 5, together about 2100 feet thick, lie parallel, and form a concentric inner band. The former contains Devonian fossils; the latter is probably of Carboniferous Age (with Lepidodendron, &c.), and forms the Wittebergen and Zwartebergen in the Cape District, and the Zuurbergen in Eastern Province. The Ecca Beds (6) come next; Lower Series, 800 feet; Conglomerate Beds (Dwyka), 500 feet; Upper Series, 2700 feet; conformable with No. 5; in the south much folded, and in undulations throughout, until it passes under the next set of beds, No. 7, in some places 50 miles to the north. The Ecca Beds have fossil wood and plant remains in abundance here and there, but these have not been clearly determined. This series has not been well defined until lately, and even now its limits are not fully determined. It includes the Karoo Desert, and therefore takes in the lowest members of Bain's great Karoo Formation, Nos. 12 and 14 of his map (1856), or the Ecca, Koonap, and part of the Beaufort Beds of Jones (1867). The series No. 7, horizontal and unconformable on the Ecca Beds at the Camdeboo and elsewhere, retains the name of Karoo Sandstones: and after a width of about 40 miles is conformably surmounted by a set of somewhat similar beds (8) in the Stormberg; and thus No. 7 should be regarded as the Lower, and No. 8 the Upper, Karoo Sandstones. The latter end off northwards in the Drakensberg, Natal, Orange Free State, the Transvaal, and Zululand, with the still horizontal Cave Sandstone and associated beds. The Lower Karoo Sandstones probably thin away northwards beneath the others. Below the Karoo Sandstones, and dying out southwards near the Camdeboo (Prof. Green), are the Shales (7*), which constitute the country around Kimberley, described as the Olive Shales of the Karoo Formation by G. W. Stow. These die out northward against the old rocks of Griqualand-West and the Transvaal. They contain Glacial Conglomerates in their lowest (earliest) beds, in Griqualand-West, just as the Ecca series has its great Glacial Conglomerate (the Dwyka Conglomerate in No. 6) in its lowest portion. As the Stormberg Beds (8) lie upon the Olive or Kimberley Shales (7*) in the Orange Free State, the Lower Karoo Sandstones (7) must die out northwards. The Kimberley Shales contain some Reptilian bones and plant remains, and some coal on the Vaal; the Karoo Sandstones are rich with Dicynodont and other Reptilian bones, and have some Fish remains; and their upper portion (Stormberg) contains Ferns and Cycadeous leaves, and some seams of coal. A fossil mammal also has been found in this series. Throughout its range the

Karoo Series is traversed with igneous dykes. Limestones and Sandstones (9) with fossils of nearly pure Jurassic, but with some of Cretaceous type, occur unconformably in the Eastern Province. Their fossil Flora is like that of the Stormberg Beds. Cretaceous strata (10) are known on the Natal coast: and Tertiary and post-Tertiary deposits (11) form several patches on the east, south, and west coasts.

THE SOUTH AFRICAN FORMATIONS

11. Tertiary and Post-Tertiary, 100'?			
			(Unconformable on several different rocks)
10. Cretaceous			
			(Unconformable on Carboniferous?)
9. Jurassic	Uitenhage Formation	Trigonia Beds, Wood-bed, Saliferous Beds, Zwartkop Sandstone	400'?
		Enon Conglomerate, 300'	
			(Unconformable on Devonian and other old rocks in Albany)
Triassic	Karoo Beds: 8. Upper	Cave Sandstone, 150'; Red Beds, 600'; Stormberg Beds, 1000'	
	Karoo Beds: 7. Lower	Sandstones and Shales, 5000'; 7*. Kimberley or Olive Shales and Conglomerates, 2300'	
			(Unconformable on Ecca Beds in the south, and on the old Vaal and Kaap series in the north)
Carboniferous?	6. Ecca Beds	Upper Ecca Beds, 2700'; Dwyka Conglomerate, 500'; Lower Ecca Beds, 800'	
	5. Witteberg and Zuurberg Quartzites, 1000'?

SECTION G—MECHANICAL SCIENCE

On the Flow of Water through Turbines, by Arthur Rigg, President of the Society of Engineers, London.—After remarking that a strict adherence to the older accepted rules of design never produces thoroughly efficient turbines, and that in the best of such motors these rules are disobeyed, the writer pointed out how little reliable practical information can be obtained from all the voluminous literature relating to turbines. He also stated that the course of a stream flowing through the guides and buckets of a turbine had no appreciable influence upon the duty obtained, so long as one essential condition was observed—namely, that its velocity should be gradually reduced to the least that will carry it clear of the buckets. In comparing screw propellers and turbines, each were shown to possess similarities; and experiments made by the writer, and published in the *Transactions* of the Society of Engineers for 1868, were referred to as explanatory of this view of the case. It was further pointed out that there is no such thing as absolute motion, for all velocities are relative to something else; and thus in a turbine we need only concern ourselves with such diminution in velocity as occurs in relation to the earth, and not necessarily with velocities in relation to the moving buckets of a turbine. Impact was considered as a pressure due to the destruction of velocity in a direction perpendicular to a plane surface, while reaction, from a vertical stream, is the natural integration of the horizontal elements of the successive pressures which act vertically in regard to the concave surface upon which the stream is caused to flow. In most theoretical investigations it is assumed that impact and reaction are equal when a current is divided at right angles to its original course, and this condition implies that a maximum result should be obtained from screw propellers when their blades stand at 45° to the plane of rotation. But in practice an angle of 42° is found best, and this is so because impact and reaction under the conditions stated are not equal, but bear to each other the proportions of 71 to 62; and these proportions give an inclination of screw-blade of 41° by taking an experiment which corresponds most closely with the conditions of a screw propeller. The resultant due to these proportions is found to be 94·25 units, whereas if impact had been the same as reaction it would have been 100·75 units, and this is the total amount that can be aimed for in designing a screw prepeller, or pure impact turbine, where the stream is merely turned through a right angle from its original course. But if instead of turning the current only 90° it is turned through 180°, then impact and a still further reduced reaction both act vertically downwards; and it is their sum, and not merely their resultant, that constitutes the total pressure obtainable from a jet of water. Taking the standard unit employed in the experiments described, this sum is found to be 126, of which 71 represents impact, and the remaining 55 the effect of a complete reaction. Therefore, in designing a turbine or screw propeller, it would seem desirable to aim at changing the direction of a stream, so far as possible, into one at 180° to its original course, for it may be said that carrying out this view has placed the modern scientifically designed turbine in that preeminent position it now holds among all hydraulic motors.

The Severn Tunnel Railway, by T. Clarke Hawkshaw.—This paper described the Severn Tunnel Railway works, begun in 1873, and now approaching completion. The railway is being made to shorten the direct railway route between the South of England and South Wales. It passes under the River Severn about half a mile below the present steam ferry, which connects the South Wales and Bristol and New Passage lines. The river, or estuary, is about 2¼ miles wide. The length of the line is 7½ miles, of which 4¼ miles are in the tunnel which passes under the Severn. The bed of the river is formed principally of Trias rocks (marls, sandstones, and conglomerates), in nearly horizontal strata. These overlie highly inclined Coal-measure shales and andstones, which are also exposed in the river bed. The tunnel is made almost wholly in rocks of the Trias and Coal-measure formation, the exception being a little gravel passed through near the English end. The lowest part of the line is below the shoots, the deepest part of the river, where there is a depth of 60 feet of water at the time of low water, and 100 feet at the time of high water. Below the shoots, the line is level for 13 chains, rising 1 in 100 to the English end, and 1 in 90 to the Welsh end. Below the shoots, there is a thickness of 45 feet of rock (Pennant sandstone) over the brickwork of the tunnel. Under the Salmon Pool there is less cover, only 30 feet of Trias marl. Much water has been met with throughout the works, which have been flooded on several occasions. In 1879 the works under the Severn were drowned for some months by the eruption of a large land spring into one of the driftways under land on the Welsh side of the river. On another occasion a cavity was formed from the driftway under the Salmon Pool to the bed of the river, when a hole, 16 feet by 10 feet, was found in the marl. The works were flooded by the water which found an entry through this hole. It was filled with clay, and the tunnel is now finished beneath it. The quantity of water now being pumped is about 10,000 gallons per minute. Additional pumps have been erected, as the large land spring, which has been penned back by a brick wall, still remains to be dealt with. When all the pumps are available, the total power will be equal to 41,000 gallons a minute. The tunnel is for a double line of way, and will be lined throughout with vitrified bricks set in Portland cement mortar. It is being made by the Great Western Railway Company. Sir John Hawkshaw is engineer-in-chief; Mr. C. Richardson, engineer; and Mr. T. A. Walker, the contractor.

SECTION H—ANTHROPOLOGY

THE first paper read in this Section was that of Prof. Boyd Dawkins, *On the Range of the Eskimo in Time and Space*. In his introductory sentences Prof. Dawkins remarked on the importance and interest of his subject. He began his inquiry into the condition of the Eskimo by particularising those of Greenland. By the aid of a sketch-map upon the blackboard, he traced the progress of the dwellers on the Arctic shores, following them to the continent of Asia. He noted that in the

vast region which is occupied by the Eskimo the degree of civilisation is practically the same, that civilisation being of a rude nature. Speaking of their relations to other nations, the Professor remarked on the broad belt of enmity, a debatable ground, that exists between the Eskimo and the Red Indian, between whom there is no friendship. But, he said, there is a likeness between the tongues of the two races, though this does not by any means prove any affinity between them. Coming to the question of the date of the settlement of the Eskimo in Greenland, he said that Markham's assumption that they crossed by Behring Straits from Asia, being driven forth by Tartar hordes, was purely assumption, and that this opinion was not shared by Mr. Dall or himself. He held that there was proof that the Eskimo, in the year 1000, ranged farther southward than where we are now. There was reason to believe this, he said, by archæological proofs, and he maintained that the Eskimo were a retreating race, being continually driven farther north by stronger and more powerful tribes, such as the Red Indians, and that if the Arctic regions had been less inclement (this being safety to this people), before this time the Eskimo would have been exterminated by the Red Indians. Even in Asia, he said, these were a retreating race, pushed farther to north and east by pursuing tribes. The lecturer remarked on the word "kayak" or boat, used by the Eskimo, and its likeness to the word (caique) used for the same object by the Turkish people, and quoted his friend Dr. Isaac Taylor, who had traced the history of this word. He explained the etymology of this word in an interesting manner, and caused a little laughter by remarking that the boat was used by the Eskimo to carry their "wives, children, and other chattels." He said, in concluding the first portion of his inquiry, that, from proofs established, the Eskimo formerly lived in a wide range of country far more south than their present habitation, and that they were driven to the north by more powerful nations. Speaking of the range of the Eskimo in time, Prof. Dawkins made some very interesting remarks on the habits and implements of the cave-dwellers in Europe. Illustrating the artistic power of these dwellers, the lecturer pointed out an enlarged sketch of a reindeer, drawn on bone, and found in a cave in Switzerland. This sketch, he said, was perfectly natural, and was admirably done by the skin-clad artist whom he pictured. He also showed the picture of an elephant, with trunk uplifted, and mouth opened, found in a cave in Auvergne. The habits of life of these cave-dwellers in Europe, he said, were the same as those of the Eskimo, and those only of the Eskimo; their implements were the same, and he would connect them in many ways, such as neglect of the rites of sepulture, for instance. The cave-dwellers, he maintained, were in every respect similar to the Eskimo, and this bore out his theory that the latter people are a retreating race in Europe, and once lived far southward of their present range. With regard to the time at which these cave-dwellers existed, and when the Eskimo came into America, the Professor said that the former dwelt in Europe in what is known as the "Pliocene" period. He said that in his opinion the Eskimo represented as a race the ancient cave-dwellers of Europe, and as such he regarded them with interest and respect. He thought that the difficulty of the question of migration was partly disposed of by the fact that the water of Behring Straits was extremely shallow, and in concluding a most interesting address, he recapitulated the proofs that he had brought forward in order to support his assertions.

Mr. F. W. Putnam, Curator of the Peabody Museum of American Archæology and Ethnology at Harvard University, gave a short notice of *The Recent Explorations by Dr. C. L. Metz and himself in the Little Nicàmi Valley, Ohio.* The particular mounds to the singular structure of which Mr. Putnam confined his remarks he has called the Turner group. The mounds, out of one of which he had taken seventy-three skeletons, were burial mounds of the ancient Indians, and some seem to have been erected for an entirely different purpose. By means of rough sketches, Mr. Putnam illustrated the formation of these mounds. One of these seemed, from the fact that everything in it had been burnt, to be erected for a sacrificial purpose. A mass of a peculiar substance, like ashes, but which was not ashes, was found in the mound. What this substance was the lecturer did not know, but it was now being analysed by chemists. He described in detail the interior of the mounds which had been explored, noticing the covered pits which were found in them, some of these containing ashes and animal bones. A mixture of iron and gravel, forming a solid cement, was a curious feature in the mound, as the presence of the iron could not be accounted for. He said that previous explorations of the mounds had been very superficial, and had led to misrepresentation on the subject, but he had found that the removal of every inch of earth was necessary in order thoroughly to explore them, and this was done. In one mound two complete skeletons were found, in the midst of ashes. Round these were fragments of three other skeletons, and sixteen skulls, six of these latter having holes bored in them, evidently with stone drills. Scratches on the skulls showed how the flesh had been scraped away with a stone knife, and the skulls had evidently been placed round the skeletons for the purpose of ornament. Mr. Putnam said that in many respects these mounds were totally different from any that had yet been discovered and explored in this country. He showed photographs to illustrate his subject, amongst them being a remarkable specimen of art in the shape of a representation of a human face cut out of a sheet of mica. This, he said, would favourably compare with Dr. Dawkins' sketch of an elephant's head drawn by a cave-dweller of Europe. The speaker also noticed many other artistic objects, such as bracelets of copper covered with native silver, and peculiar and large earrings of the same material. In other cases he had found objects covered with native meteoric iron and with native gold; also terra-cotta images of small size, most of them much broken by the action of the fire into which they had been thrown. He remarked upon the likeness in many respects that the ornamentation of these objects bore to the work of the Egyptians.

A paper by Dr. Paul Topinard was read, entitled *Instructions anthropométriques élémentaire.* The author described various instruments that had been devised by him for enabling inexperienced travellers to take measurements of the human body with moderate accuracy.

Mr. Jeremiah Curtin read a paper *On Myths of the Modoc Indians.* He said that there were between three and four hundred Modocs, most of whom were in the Indian Territory and Southern Oregon. He proceeded to read a "myth" of these people which related to a personage called the Blue Woman, who was supposed by the Indians to be the second person in the Universe. This story, which was something like a fairy tale, was taken down in the original language by the speaker himself. He described the hardships through which the young Modocs went in order to fit themselves for manhood, such as climbing a mountain in order to reach an almost inaccessible pond, in which they swam.

SCIENTIFIC SERIALS

Journal of the Russian Chemical and Physical Society, vol. xvi. fasc. 6.—On the succession of reactions, by M. Lvoff, being an introduction into a series of researches undertaken by the author and several students, in order to disclose the mechanism of polymerisation.—On the action of chlorine on butylenes, by M. Chechoukoff.—On constants of chemical affinity, by W. Ostwald. The author, who maintains the views of Berthollet, further elaborated by Guldberg and Waage, considers that there is, for each body, a certain numerical coefficient of its chemical affinities as characteristic for the body as its atomic weight; and in addition to his former works, already published in the *Journal für pract. Chemie*, he publishes now a preliminary list of "constants of chemical reactions."—On glycidic acids, by P. Melikoff. —On the displacement of chlorine by bromine, and an explanation of the reactions which are accompanied by a disengagement of heat, by A. Potylitzin. The substitution of chlorine by bromine, in seeming contradiction with the law of maximum work, and which Berthelot has endeavoured to explain by the formation of chloric bromine and bromides of metals, could be explained by admitting that the reaction is going on with the heat received from the surrounding medium. This important inquiry, pursued by the author for several years past, brings him to interesting conclusions on thermo-chemistry.—On asarone, by MM. Rizza and A. Butleroff, being an inquiry into the properties of the camphor received from *Asarum europæum.*—On a new apparatus for determining specific heat, by W. Loughinin. It is a modification of the apparatus of Neumann.—On the reduction of isodinitrobenzyl, by P. Goloubeff.—On the preparation of animal colouring matters from albuminoid substances, by W. Mikhailoff.—On azophenylacetic acid, note by M. Wittenberg.—On the solution of lithium carbonate in water, note by J. Bevad.—On a hygienic photometer for schools, by Prof.

Petroushevky. It allows the amount of light received by books, paper, &c., on the desks of scholars, to be rapidly and accurately measured.—On the volume of a liquid considered as a function of temperature under a constant pressure, by K. Jouk. Diethylamine and ethyl chloride both agree with Prof. Avenarius's formula: $v = a + b \log (\tau - t)$.—On the relation between pressure and the density of rarefied gases; preliminary communication by K. Kraevitch.—Notes on the structure of the atmosphere, by MM. Stankevitch and Rogovsky.

Annalen der Physik und Chemie, No. 7, June 15.—On the electric discharge in gases, by O. Lehmann (2 sheets of figures).—Contribution to the investigation of the origin of thermo-electric streams in a continuous homogeneous conductor, by Rudolph Overbeck (10 figures).—On the changes which the molecular structure of iron undergoes by heating and cooling, by Carl Frounne (2 tables).—On the appearance of electricity with the development of gases, by W. Hankel.—On a constant battery for electrical measurements, by W. von Beetz.—On the position of the pole, the induction and temperature coefficient of a magnet, and on the determination of the magnetic moment by bifilar suspension, by F. Kohlrausch.—On the dispersive power of a diamond, by A. Schrauf.—Researches on radiant heat, by Heinr. Schneebeli.—On the construction of Bohnenberger's reversible pendulum for the determination of the length of a pendulum for observing the period of oscillation in relation to a given length of mass, by Wilhelm Weber.—On the equilibriums of floating elastic plates, by H. Hertz.—The electricity of flame; reply by J. Kollert.—On a new position for the measuring wire in the Wheatstone-Kirchoff bridge combination, by Hugo Meyer (2 figures).—Wheatstone's rheostat and mercury contact, by J. Bodynski (2 figures).

Journal de Physique théorique et appliquée, July.—On the analytical expression of absolute temperature and Carnot's function, by G. Lippmann.—On the electro-chemical equivalent of silver, by M. Mascart.—On the phenomenon of crystalline overheating of sulphur and the rapidity of transformation of octahedral to prismatic sulphur, by D. Gernez.—Study of the distribution of potential in conductors of two or three dimensions traversed by continuous currents, by A. Chervet.—On an electrostatic standard of potential, by Messrs. Crova and Garbe.—On the variation of the capillary constant at water-ether and water-carbon bisulphide surfaces under the action of an electromotive force, by M. Kronchkoll and Lord Rayleigh.—On the electro-chemical equivalent of silver, and on the absolute electromotive force of Clark cells, by B. C. Damien.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 22.—M. Rolland, President, in the chair.—On algebraic equations: part third, on irrational equations, by M. de Jonquières. The author arrives at the somewhat unexpected conclusion that all algebraic equations, whether rational or not, which belong to the same "species," possess the same maximum number of real roots, whatever be their respective degrees.—Observations on the corona now visible round the sun; variations in its form and colour; a method of increasing its luminosity; polariscopic observations; polarimetric and photometric observations, by M. A. Cornu. The author is still disposed to connect this phenomenon with the Krakatoa eruption. The facts adduced are regarded as numerous enough to support the natural hypothesis of a cloud of particles with a nearly constant mean diameter, projected by the volcano and held in suspension in the higher regions of the atmosphere.—On the general evolution of the vegetable functions in annual plants: the Amaranthaceæ, by MM. Berthelot and André.—On the movement of Hyperion, by Prof. S. Newcomb. The author concludes that all the conjunctions of Hyperion with Titan take place near the aposaturn of the latter satellite. The point of conjunction oscillates about 180° on either side of the aposaturn during the period of revolution of the perisaturn of Hyperion in relation to that of Titan.—On the completion of the new method for resolving the most general linear equation into quaternions, by Prof. Sylvester.—Remarks on the third instalment of the new topographical map of Algeria presented to the Academy by Col. Perrier. This section consists of six sheets, comprising Miliana (province of Algiers), Saint Denis-du-Sig (province of Oran), Herbillon, Cap-de-Fer, Cap-de-Garde, Bugeaud (province of Constantine). The surveys are executed on a scale of 1 : 40,000, and the map, engraved on zinc, is issued at the scale of 1 : 50,000. Each sheet comprises seven plates, the relief being figured geometrically by equidistant curves of 10 m. in 10 m., and the plastic disposition of the surface being obtained by means of a dubbed drawing with lithographic crayon, based on the zenithal light and heightened by a slight touch of oblique light. The map marks a great improvement in the cartographic art.—On a development in a continuous fraction, by M. Stieltjes.—Note on the antiseptic properties of the sulphuret of carbon, by M. Ckiandi-Bey. From numerous experiments carried on for several years, the author finds that this sulphuret, which is soluble in water, arrests all fermentation, kills all microbes, is a most powerful antiseptic, and is, moreover, endowed with considerable penetrative power. Hence he strongly recommends it as a most efficacious remedy for cholera, typhus, diptheria, phthisis, and all diseases traceable to living germs.—Contributions to the study of the Cretaceous flora of the west of France, by M. L. Crié.—The Perpetual Secretary announced to the Academy that the International Committee of Weights and Measures representing the high contracting parties to the Convention for the Metre signed at Paris on May 20, 1875, has received the adhesion of England, which had hitherto taken no part in the Convention. With the further accession of Roumania and Servia the Committee now represents an aggregate population of 421,440,396, distributed over Germany, England, Austria, Hungary, Belgium, the Argentine Republic, Denmark, Spain, the United States, France, Italy, Peru, Portugal, Roumania, Russia, Servia, Sweden, Norway, Switzerland, Turkey, and Venezuela.—The photolithographic facsimile of a letter addressed by Gauss to Olbers on September 5, 1805, was presented to the Academy by Prince Boncompagni.

THURSDAY, OCTOBER 9, 1884

THE CHOLERA POISON

THE reporter of the French Commission appointed to investigate the mode of action of the cholera poison and its method of propagation, as judged of from the behaviour of the disease during the epidemic in the southern provinces of France, has made public the conclusions which have been arrived at. It will be remembered that the French Commission which studied the same subject in Egypt last summer differed from the German one in regarding the blood as containing the specific organism of the disease, a contention which found no support in this country when the medical societies had had an opportunity of examining microscopically the preparations which were supposed to afford proof of it. Dr. Koch, chief of the German Commission, on the contrary, declared that the French statement was due to an error of observation, and maintained that the comma bacillus which he had discovered in the coats and contents of the intestines formed the specific germ of the disease. The French Commission of 1884 now return to the subject by still maintaining that the blood contains the poison, and that the initial lesion of cholera takes place in the blood. In proof of this they describe the changes which the blood cells undergo during the process of cholera; they regard certain modifications, such as result from the entire loss of elasticity of the globules, as one of the most certain signs of the patient's impending death; they maintain that by the hourly examination of the blood of cholera patients the progress of the malady can be mathematically followed; they assert that cholera, as such, is transmissible to the rabbit as the result of the injection into its veins of the blood of a cholera patient at the algid period; and lastly, they maintain that the microbe specially described by Dr. Koch has no such specific properties as have been claimed for it.

So far the two sets of observations are diametrically opposed to each other, and neither of them finds much support from the investigations of Drs. Lewis and Cunningham in India. The French contention that cholera is transmissible to one of the lower animals is at variance with all previous trustworthy experiments, and until the details of the method of operating and of the symptoms induced are made public, it would be premature to accept the conclusion at which the Commission have arrived at as in any way proven. But, on the other hand, time is not lending support to the contention of the German Commission, and it is asserted that the early labours of Dr. Klein in Calcutta have confirmed the view which he has all along held, that the announcement of the discovery of a specific cholera organism in the comma microbe is, at least, premature. Fortunately, many observers are now at work in the field of cholera micro-pathology, and the opportunities which have been, and still are, afforded for such work both in Europe and in India are exceptionally favourable. The interests of science will be best observed by waiting for the results of the labours now in progress, and by the exercise of caution in accepting any views which are based on any isolated series of experiments. But whatever be the result, Dr. Koch and the German Commission must be regarded as having given fresh life to a scientific question the interest in which had for some time past been flagging, and to them must be given the credit of having secured in Dr. Klein's work at Calcutta the establishment of an English laboratory for the elucidation of a subject which this country should always regard as peculiarly its own, in view of the fact that among its possessions is the country which has always been regarded as the home of cholera.

THE SANITARY INSTITUTE AT DUBLIN

THE Sanitary Institute of Great Britain succeeds, by its annual migrations from town to town, in securing a widely-diffused interest in matters relating to public health, and there are but few large towns in the United Kingdom that stand in greater need of some such stimulus than Dublin, where, under the presidency of the veteran sanitary engineer, Sir Robert Rawlinson, C.B., the Institute has met this autumn. Within the past twelve years we have made great strides in organising a sanitary administration in this country, every portion of which is subject to the control of a sanitary authority having at least two executive officers—the medical officer of health, who is intended to be a skilled adviser as to the principles which should be held in view in action taken for the promotion of health; and an inspector of nuisances, whose functions relate in the main to the periodic inspection of his district with a view of the removal of such conditions as are likely to cause injury to health, or nuisance. In Ireland a somewhat similar organisation has also been established, and, as in this country, the working of the system is subject to the control of a central body known as the Local Government Board. But to judge from a paper read before the Institute by Dr. Edgar Finn, there is a wide difference between the efficiency of the two systems, and it is certain that, whether judged by the progress that has actually been made or by the amount of money that has been raised by way of loan for the execution of sanitary works in England and in Ireland, the latter country must be regarded as comparing very unfavourably with the former.

According to Dr. Edgar Finn, this is partly due to the fact that the Irish Local Government Board is in itself unmindful of using the ordinary means at its disposal for enforcing the proper carrying out of the provisions of the Act under which it is constituted, partly to the circumstance that in the large mass of the sanitary districts the Boards of Guardians who have been constituted the sanitary authorities take but little interest in their sanitary duties, but mainly to the faults inherent to the system under which the medical officers of health are appointed in the rural districts. In Ireland the dispensary or poor-law medical officers are appointed to act as rural medical officers of health, and Dr. Finn points out that the miserable addition of from 10*l.* to 15*l.* to their other salaries does little more than suffice to induce them to hold their tongues, and to take no official notice of the conditions of dirt and unwholesomeness with which they come into contact. And not only so, but it is alleged that such officers cannot possibly be unfettered and independent in their action, for they are generally the medical attendants of the Guardians whom they serve, and who

are probably in most cases the owners of the properties needing sanitary amendment. In England, on the contrary, Dr. Finn points to the frequency with which rural sanitary authorities combine amongst themselves, and at times also with urban authorities, in the appointment of a single officer of health, to whom it is then possible to give such a salary as will command the entire services of a really competent and independent officer. The contention is true to a certain extent, but it must be remembered that the same system which Dr. Finn describes as faulty in Ireland is precisely the one which the poor-law inspectors, to whom the English Local Government Board originally looked for advice in this matter, secured throughout a very large portion of England when first the appointment of medical officers of health became compulsory in 1872, although it is true that the same Board has during the past five or six years been striving its utmost to undo the arrangement then carried into effect. It was originally felt that a local officer whose other duties necessitated his constant presence in every portion of his district would be the most competent of all to advise as to its sanitary circumstances, the more so as he, of all others, would have the earliest information as to the existence of preventable sickness and death. At first sight the idea seems a very plausible one, and if the principal duties of an officer of health were to be performed on the occurrence of disease, it might still find intelligent supporters. But it is essentially the prevention of the conditions leading to such diseases, and not their remedy after the disease has occurred, that should be looked for from the officer of health, and it is daily becoming more and more apparent that wider districts, supplying wider experience and commanding more skilled services, tend to this, rather than narrow areas which are only looked after during the performance of multitudinous duties of a more pressing character. It is not that the dispensary or poor-law medical officer is necessarily incompetent to perform the duties expected of an officer of health, for in England such officers at times hold both appointments with considerable advantage; but the great mistake which was originally made in England, and which has been repeated in Ireland, was to regard men as competent to perform the duties of one office merely because they held another office involving the performance of totally different duties.

The present is, however, a period of transition in this matter, and the public cannot expect to secure the highest procurable services until degrees and diplomas in sanitary science shall be so universally taken by those who seek public health appointments, that it shall always be possible to find candidates possessing the needful guarantee that they are competent to perform the duties of medical officer of health. The principle of combination by several authorities to secure the entire services of a single officer of health over a reasonably large area tends to efficiency, and most of such officers recently appointed have been able to prove their fitness for the post by the possession of some such diploma as we have referred to, and which can now be procured in each of the three divisions of the United Kingdom.

We have given this matter some prominence because of the importance which attaches to it wherever medical officers of health are appointed, but the Institute dealt at Dublin with many other subjects which are of equally pressing importance in Ireland. The need for improved dwellings for the poor, for adequate supplies of wholesome water, for efficient means of drainage, and for some proper methods for the disposal of refuse, are urgent requirements in many parts of Ireland. The lack of them causes needless mortality and sickness, and the methods by which they may best be supplied were fully indicated. As a test of the needs of the country in these respects, statistics as to deaths and sickness need to be intelligently examined, and amongst the contributions to the Congress few papers were of more value than that in which Dr. Grimshaw, Registrar-General for Ireland, dealt with the statistical measures of the health of communities, and so explained how a proper estimate of the health of a district may best be arrived at.

CONTRIBUTIONS TO PHENOLOGY

Beiträge zur Phänologie. By Dr. Egon Ihne and Dr. Hoffmann. (Giessen: Published by the Authors, 1884.)

PHENOLOGY, the observation of the first flowering and fruiting of plants, the foliation and defoliation of trees, the arrival, nesting, and departure of birds, and such like, has attracted the attention of naturalists from time to time for nearly 150 years. Some have continued their observations for several years and have formed therefrom a "Calendar of Nature"; others have gone still further and have tried to deduce more general results. But the subject is beset with difficulties, especially when an observer endeavours to procure the aid of others, and this has proved so great at times that the work has not flourished as much as it deserved. The subject has been most carefully studied by M. Quetelet of Brussels, and his writings have served as the basis for most of the subsequent attempts which have been made at organising a System of observation. Dr. Egon Ihne of Giessen, in connection with Dr. Hoffmann, whilst endeavouring to form a series of Charts of plant-flowering for Europe generally, has consulted all accessible works likely to contain any information on the subject. This information is most generally scattered through the Transactions and Reports of Botanical and Local Societies, but still there is much to be obtained from other works, whose titles would not lead one at first to consult them for the purpose. The number and minuteness of the notices mentioned by these Professors, shows that they must have spent a long time in preparing this work, and very valuable service has been rendered to Phenology by publishing the list of sources from which information can be obtained. The total number of works noticed is 196, and naturally those published in Germany are most numerous. It will, however, surprise many to find that, whilst 102 German works are noticed, Great Britain with only 21 comes next, leaving 73 for the rest of Europe. It must be evident, therefore, that, notwithstanding the great care taken in compiling this list, there must be many works not noticed which contain phenological information, and the Authors would doubtless welcome notices of any works omitted from their list.

The main part of the book consists of a short account of the progress of Phenology in each of the countries of Europe, followed by a list of the works published in that country, with such short notes as may suffice to explain the nature of the information each contains. To this is

added a very complete index in two parts. The first part gives a list of the stations at which observations have been made, arranged alphabetically under the names of the countries of Europe in which they are situated; the total number of such stations is 1926. The second part consists of the names of these 1926 stations arranged alphabetically, with the years in which observations have been taken, and references to the works in which these observations are recorded. Some very curious facts may be obtained from this index. Whilst there are 315 stations in Great Britain, there are no less than 918 in Germany and Austria, and consequently 693 for the rest of Europe. But a more critical examination of the list reveals the fact that, of these 1926 stations, only 334 were taking observations in 1882, the date of the compilation of the work, and at only 97 of these 334 stations had observations been continued for ten years or more. Even this small number requires modification, for out of the 97 only 60 had observations for ten *consecutive* years, thus showing how spasmodically the subject had been treated till quite a recent date. Of the 1592 stations at which observations have ceased, there are only 210 with records of ten years and over. Considering the nature of the subject, ten years' work must be considered as the very least from which anything reliable may be deduced; whence, small as the number is compared with the large number of stations at which phenological work has been done, it is yet satisfactory to find that there is some good material to be obtained. Of late years the subject has been much more attended to, especially in England, since the Royal Meteorological Society took the matter in hand, and of the 334 stations at which observations are now taken, no less than 94 are in Great Britain and 112 in Germany.

Dr. Ihne regrets that the observations as taken for the Royal Meteorological Society refer to herbaceous rather than woody plants, and are exclusively confined to wild flowers and not to cultivated ones. His own list, which has been very generally distributed throughout Europe, has been drawn up on a different principle, and without entering into definite reasons, he condemns the Meteorological Society's list. Certainly in England, in the only case besides that of the Meteorological Society where a comparison of flowering throughout England has been tried, cultivated plants have been entirely excluded, being found by actual experience to yield no reliable results.

The second part of the work is taken up with an enumeration of the notices on the plants in the list issued by the Professors taken during the years 1879 to 1882. It would have been perhaps more convenient if they had been exhibited in a tabular form; at present it would be a work of some labour to extract the notices for the purposes of comparison.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Younger School of Botanists

A COMMUNICATION from the Rev. George Henslow to last week's NATURE (p. 537) concludes with the following passage:—

"There are not wanting signs elsewhere of the evil effects of the younger school of botanists not recognising the importance of first training students in a thorough course of practical and systematic botany before proceeding to laboratory work. In an examination lately held for a post at Kew, I am informed that two gentlemen who had been trained at Cambridge competed with a gardener for the post. The gardener secured it. *Verb. sap.*"

The last sentence is no doubt intended as a sort of *argumentum ad hominem*, which it may be admitted is not without a certain apparent force. Assuming for the moment the statement to be true, it must be pointed out that the only scientific posts at Kew which are open to public competition are those of assistants in the herbarium. These posts demand qualifications of a somewhat technical character, for which a general training in botany would by no means necessarily fit the candidates. I can imagine that a senior wrangler might fail in a competition for a post of computer in an observatory where arithmetical dexterity was the main thing required; a senior classic might cut an equally poor figure in seeking an appointment of library assistant if he were tested in the art of writing catalogue slips. I apprehend that in neither case would failure prove anything as regards either mathematical or classical education.

The examination to which Mr. Henslow alludes can only be one which was held by the Civil Service Commission during the past summer. There were, I believe, some dozen candidates; whether any Cambridge men were amongst them I am unable to say. But the successful candidate was not a gardener, but the laboratory assistant of the late Professor of Botany at Oxford—a gentlemen whose services the present Professor is in despair at losing.

On a former occasion it is true that one of our garden staff did obtain one of these appointments in an open competition. It is not very remarkable that it should be so. Men of ability on the spot have, of course, great facilities for seeing the nature of the duties required and for qualifying themselves accordingly; furthermore they have the advantage of the lectures of my colleague Mr. Baker, which are especially directed to the branch of botany which principally occupies us at Kew.

As to the larger question raised by Mr. Henslow, I am afraid I am not wholly free from some responsibility for the proceedings of "the younger school of botanists," the effects of which he regards as evil. In the face of the successful revival in this country of many branches of botanical study which the younger school has effected, I am emphatically of the opinion that these effects are the reverse of evil. I believe I was one of the first to organise a course of so-called laboratory work in botany on lines which it is only right to say were borrowed and extended from the teaching and example of Prof. Huxley. In what I attempted I had the generous aid of many now distinguished members of the younger school. I do not doubt that they have immensely improved on the beginning that was in the first instance somewhat tentatively made. But the principle, I believe, has always remained the same, namely, to give the students a thorough and practical insight into the organisation and structure of the leading types of the vegetable kingdom. When, therefore, Mr. Henslow, himself a teacher, asserts that such laboratory teaching as this should be preceded by a thorough course of practical and systematic botany, it appears to me that he is bound to explain what he precisely means by this very dark saying. For, if botanical laboratory work in this country is not thorough, is not practical, and, in dealing with types drawn from every important group, is not systematic, it is important to know in what respects it falls short of these requirements.

W. T. THISELTON DYER

Royal Gardens, Kew, October 4

The Solar (Dust?) Halo

THE reddish halo to which Mr. Backhouse draws attention in his letter of September 20 in NATURE (p. 511) has of late been noticed by several observers, and this I think is because, while the sunrise and sunset glows have exhibited a marked decline in their duration and brilliancy since last winter, the halo has shown no similar diminution of intensity, and thus attracts more attention relatively than it did at first, when it remained for some time almost entirely unnoticed in this country. In reply to Mr. Backhouse's question as to whether this halo has been seen in England previous to last November, I have a very strong impression that it made its first appearance here coincidently with

the arrival of the unusual sunsets last year, and that it has never been seen here before, at any rate within the last twenty years. This impression is founded, first, on the fact that, like Mr. Backhouse, I have been in the habit of frequently looking at solar ha'os for years past. Secondly, I have been engaged since September 8 last year in a series of observations with anemometers attached to a kite-string (latterly wire), which has naturally necessitated my frequently looking up at the sky. I remember noticing the halo in November, and calling the attention of my assistant to the beautiful salmon colour it showed in the interstices of a mackerel sky, which shut off the direct glare of the sun.

On several occasions I measured its radius with a theodolite I was using, and in every case the value came out either 22½° or 23°. It must therefore be due, like the ordinary ice-halo, to refraction through hexagonal prisms. I noticed it all the way going out to America in August last, and saw it beautifully when standing on the Terrapin Bridge over Niagara Falls on August 23. A large black cloud had shut off the sun's glare, and the red border happened just to coincide with the edge of the cloud. I called the attention of some American ladies to the spectacle, which they had of course never noticed before, and which they admired immensely. I regard the sunset glows as partly an intensification of the halo, produced by the greater thickness of the stratum through which the refraction takes place when the sun is below the horizon (the sunset, in fact, being formed of the upper half of the halo which lingers behind) plus reflection from the same stratum, which can of course only come into operation when the sun shines obliquely on it. The fact of the halo remaining constant while the sunset glows have become weaker may be readily explained on the hypothesis that the stratum has gradually sunk to a lower level than it had last winter, since the duration and even brilliancy of the glow must of course vary directly with its height, whereas the halo at midday need not be sensibly altered by a variation in its level.

Three weeks ago yesterday, I saw the sun rise from the summit of Mount Washington, 6293 feet above sea-level, and at ten minutes to five o'clock saw, in addition to the usual sunrise effects, a large circle of rosy purple haze situated about 15° above the horizon, and apparently having no connection with the yellow and red horizontal bands beneath it. The morning was exquisitely fine, the only clouds being a few light streaky cirro-strati, as shown in diagram, and the air was as clear as it only can be in America. I may add that the haze circle appeared almost suddenly after the first yellowish light had been visible for twenty minutes, and as soon as the sun rose above the horizon it seemed to vanish almost entirely. I have seen the sun rise from various altitudes up to 12,000 feet, but I never saw anything so curious as this sunrise before. In fact, I went up mainly to see it, and was not disappointed.

Cole's Pits

YOUR note on the result of Gen. Pitt-Rivers' examination of the Pen Pits (Somerset) in this week's number of NATURE (p. 545) reminds me of a series of similar pits in this county of Berks, known as "Cole's Pits." They are situated near the branch of the Great Western Railway which runs from Uppington to Faringdon. I have visited them more than once when on visits to Wadley, the residence of my friend Mr. T. L. Goodlake, J.P. They correspond generally with the description given in NATURE of the Pen Pits, are probably of quite equal extent, are similarly situated on rising ground forming the cap of a ridge of hills, and are on the same Greensand formation. Many and various theories have been propounded from time to time by antiquarians, and of course the name by which these pits have been known for generations has been appealed to as connecting them with the "merry King Cole," and giving support to the views of those who regard them as traces of an "ancient British town." The utter absence of order in the arrangement of these shallow holes and rude mounds (for they are nothing more) excited my suspicion, nor could I see much in them to suggest occupation by any race which has inhabited these islands even so late as the time of the ancient Britons. On further investigation of them I came across a more modern sort of hut, consisting of a space rudely roofed over, the back of which was cut into the side of one of these grass-grown banks. The idea occurred to me that this would help to furnish evidence, since, if these hollows were dug in the strata of the hill to be roofed over for human habitation (the notion which, I am told, finds general favour) we ought to find some traces of *stratification* in a section thus presented to us. Not a trace of this was to be found; the section showed nothing but a chaotic mass of rubbly material with no more order in its arrangement than is to be found in the waste heaps of any old quarry or in a terminal moraine.

So far one's first impressions of the "pits" and mounds, as of an extensive series of old disused quarries, received confirmation. I cannot hazard a conjecture as to the extent to which quern-stones may have been obtained from the "Cole's Pits"; but it seemed to me extremely likely that the range of hills in question, here so many hills on sandy formations (our Bagshot Sands, for example) owed its existence, *quâ* hills, to the protection of the hard "paw" which is so frequently met with in such formations, which I have attempted to account for in the *Proceedings* of the Geological Association (vol. viii. No. 3), and which was certainly largely worked in places for rude building construction in very early times, large masses of it being seen still in the old Roman wall which to-day completely encircles the area occupied by the ancient town of Silchester. It is possible, too, that such ironstone may have been rich enough in the metal to serve as ore, when iron "forges" were common in past centuries in the forest districts of the south of England. Further support is given to the view which I venture here to put forward as to the origin of the Cole's Pits, by the fact that lower down the hill, and at a rather lower "horizon," there is a sand-pit open in the side of the hill, in which thin bands of ironstone occur, some of which, to judge from their specific gravity, might certainly have been available as ore, under conditions which obtained in the iron industries of the country a few centuries ago.

The Flow of Streams

THE observations made by Mr. Maw on a stream flowing into the Lake of Thun are an extremely interesting example of well-known hydraulic laws. It would be well, however, if he would tell us what was the depth of the water; from the observed phenomena I presume it was small. Mr. Smith's very ingenious mode of practically showing the different strengths of a current from surface to bottom should also be supplemented by an account of the size of the stream operated upon. The situation of the point of greatest velocity varies considerably with the conditions of the river or stream, and is by no means fixed. The observations made on some large rivers, notably those by Mr. Revy on the large rivers of South America, seem to show that the greatest velocity is, in such cases, almost, if not quite, on the surface, and that from that point it diminishes uniformly downwards to the bottom. The ratio between the surface and bottom velocities is, however, a constantly changing one, and in large rivers varies with the depth of the water. Mr. Revy's observations seem to show that in large rivers, where the influence of the banks is practically inappreciable, the surface velocity varies directly as the depth, whilst the bottom velocity varies as the square of the depth; as the depth increases, the difference between the top and bottom currents diminishes, until at a depth of about 71 feet they are practically equal. These results are borne out by the observations of Messrs. Humphreys and Abbott on the Mississippi and Mr. Gordon on the Irrawaddy. All observations to be useful, therefore, should give the size of the river or stream operated on. If Mr. Smith has not seen the diagrams given by Mr. Revy in his "Hydraulics of Great Rivers," I think he would be interested in them.

GEORGE HIGGIN

Lepidoptera

I AM at present carrying on some researches here, for which a supply of living caterpillars of such large Lepidoptera as the Death's Head, Goat, or Hawk Moth is necessary. As I have had some difficulty in obtaining these, I should feel exceedingly obliged to any of your readers who may find or possess larvæ of the above or other large species, if they could furnish me with specimens.

Animal Intelligence

MR. HARRISON, like most of those who deal with animal communications, assumes that sounds or words must form the basis. This rests upon the assumption that speech is a primary system of communication for mankind, instead of being secondary. Many babies will begin with sign communication, and show a preference for it after they are well able to articulate words. The dog will follow human gestures as well as sounds and words. It is indeed worthy of consideration how far signs play a part in communication between animals. Instead of supposing a complicated system of words, as Mr. Harrison does, it is easy to conceive that, with the apparatus he describes, many signs may be made. Expressions of alarm, joy, direction, can be as well made with antennæ as with hands.

32, St. George's Square, October 6 HYDE CLARKE

Shifting of the Earth's Axis

PERMIT me to say that it was from the diagrams in the paper by Mr. Christie which he quotes (NATURE, October 2, p. 536) that I drew the conclusions of decrease of latitude. In the fuller statement to which I referred, I had expressly said that it was from the Polaris observations that a decrease of latitude might be deduced. The question turns on whether the truest result is obtained by trusting entirely to Polaris, or by including other stars which are at greater N.P.D. and have more variation in the refraction: as the former is less dependent on the most uncertain element of reduction—refraction—I inclined to rely on it entirely. It would be remarkable if the great oceanic circulation should have a mean axis of motion so nearly coincident with that of the earth as not to produce 1/100th of a second change in the Pole during half a century; the presumption would seem against such a fixity. W. M. FLINDERS PETRIE

Bromley, Kent

To Find the Cube of any Number by Construction

CAPT. H. BROCARD (of Montpellier), writing to me on the subject of my note in last week's NATURE (p. 539), communicates the following two simple constructions: —

1. On two rectangular axes Ox, Oy, take A on Ox and B on Oy, such that $\angle OAB = \alpha$, through B draw $BC \perp^r$ to AB, meeting OX in C, and draw $CD \perp^r BC$, meeting OY in D: join AD. Then $\tan OAD = \tan^3 \alpha$.

2. Take $BOD = \alpha$, from A on OD erect $\perp^r$ to meet OB in B: draw $BD \perp^r$ to OB, and let fall $AC \perp^r$ to BD. Then if we take $OA' =$ unity (A' is the projection of A on OB), $BC = \tan \alpha$, $A'B = \tan^2 \alpha$, $CD = \tan^3 \alpha$.

It may be of interest to note with reference to the figure indicated in my construction, that M. Brocard finds that if $FK \perp^r FD$ meets CB in K, and $KL \perp^r FK$ meets FO ($\perp^r BC$) in L, then LD passes through H.

October 6 R. TUCKER

THE ASCENT OF WATER IN PLANTS

THE fact that water is taken up by plants and passes off as vapour at the leaves is one of the best known data of vegetable physiology. The current of water passing up the stem of the transpiring plant is known, moreover, to be copious and rapid, and to pass through certain parts of the wood only. Apart from other questions, it has long been sought to explain by what forces this current can be maintained in the plant, and the difficulties which have arisen and been surmounted have been many; certain of these difficulties, however, are still outstanding.

It was an immense stride forwards when the fact was demonstrated that the water absorbed by the roots passes up the stem in the younger wood; and when it was recognised that in the Conifers this consists of definite elongated cells, not openly communicating, and is not complicated by the presence of vessels, &c., the problem promised to be much simpler.

As is now well known, the earlier hypotheses which were made to explain the ascent of water in transpiration have been long put aside, as new facts were observed which could not be satisfactorily explained by them: the old theory of capillarity succumbs evidently to the facts; and Quincke's hypothesis, though less easily despatched, must also be relegated to the list of past errors.

Two theories, or rather hypotheses, have attracted so much attention lately, that we may fairly regard them as the two rival views for the explanation of the ascent of the transpiration current. The one, especially advocated in its earlier shape by Boehm, seeks to explain the ascent as due essentially to the pressure of the atmosphere acting on a system of air-bubbles and water which can be shown to exist in the plant: this hypothesis, but shortly stated here, is obviously in contradiction to several important facts, *e.g.* the height of tall trees, and the difficulty of explaining how the atmospheric pressure could act on the closed system of the plant.

The second, and very different hypothesis, is the one recently proposed by Sachs. Assuming that the molecules of water imbibed by the wood cell-walls are held between the complex molecules of these walls in a peculiar condition—very much, in fact, as salt molecules are held between the molecules of water in the sea—then the difficulties in connection with tall trees disappear; for by the peculiar properties of the wood cell-walls it matters not whether a given molecule of water is a yard or a hundred yards high. This hypothesis undoubtedly explains numerous facts, and, if choice lay between it and the theory of atmospheric pressure only, no doubt could exist as to which we should accept; nevertheless, there are objections to it apart from the assumption of such very peculiar properties of lignified walls.

Before saying anything as to the possible modifications of the former theory, it will be well to see how it arose in the first instance.

Jamin, in the *Comptes Rendus* for 1860, published an investigation on some capillary phenomena, and particularly on the behaviour of capillary tubes containing air-bubbles in addition to water.

Suppose an open capillary tube of glass filled with alternating drops of water and bubbles of air. If pressure is exerted at the one open end of such a tube, of considerable length, it is observed that the pressure is not transmitted simply through the system, but that each successive one of the alternating columns of water causes a lessening of the effect. Of course each column of water, between two air-bubbles, has two concave ends, and the changes produced in these can be observed. Without here going into the explanation of this phenomenon of the apparent disappearance of the pressure, it suffices for our purpose that an open column consisting of air-bubbles alternating with drops of water may be placed upright and the water not flow out. Jamin showed that with long tubes, the water-columns of which were sufficiently broken by air-bubbles, even a pressure of three atmospheres applied to one end failed to move the lower parts of the column. Such a column of alternating drops of water and air bubbles is called a "*chapelet de Jamin*."

It is known that porous bodies, such as gypsum, absorb water with great force: such bodies when saturated with water are very impervious to air, a fact which may be illustrated by means of the wet linen in any wash-tub. Jamin even proposed an explanation of the ascent of water in accordance with these facts, regarding the wood simply as a porous body.

It is not necessary to go into details as to the various modifications of the theories which in any way depended upon ordinary capillary phenomena; enough that the objection that, even if the plant had capillary tubes sufficiently fine to support the water columns required by a tall tree, the water could not flow through them so rapidly as the requirements of respiration demand seemed fatal to any of these theories, and made Sachs's assumption of the extraordinary properties of wood cell-walls appear the more necessary. Moreover, the Conifers have no such capillary tubes in the secondary wood.

It is impossible to put in a short space all the reasons which led Sachs to draw a sharp distinction between the behaviour of water entering into preformed capillary cavities or interstices, and water which is "imbibed," *i.e.* forces its way between the molecules or micellæ of an organised body. It may be remarked that cases may easily be supposed where it would be difficult to draw the line, and it is certainly not easy to see why "imbibed" water should be held less fast than water in capillary interspaces. It is just here, in fact, that the assumption of the extraordinary conductibility of wood comes in.

It is clear, then, that the great difficulty which is to be put aside by assuming, with Sachs, that the water of transpiration is held in a peculiar mobile condition in the substance of the cell-walls, is that of accounting for the great height of the water columns in tall trees. The old capillary theory will not explain this away, because, although the requisite columns of water could be *supported*, the water could not be *moved* as required.

Frederick Elfving brought forward an awkward objection to Sachs's theory a couple of years ago. By stopping up the lumina of the cells and vessels in such a manner that the edges of the cut elements could still be exposed, it was shown that no water could be pressed through a piece of wood. He showed, moreover, that coloured solutions passed into the cavities of the wood-cells through the thin membranes of the bordered pits, but—as must be concluded from his results—not through the thick substance of the walls. Objections have been raised to some details, but it seems difficult to avoid the conclusion that Elfving's results contradict every other view than that the water passes through the thin membranes of the bordered pits, and through the cavities of the elements, and not through the main substance of the walls of the lignified cells.

Elfving has recently published a paper on this subject ("*Acta Soc. Scient. Fen. nicæ*," t. xiv. 1884) proposing an important modification of the views hitherto held. It is needless to go into the reasons why the theory of gaseous pressures generally must be abandoned, even in its later form, as was Boehm's air-pump theory before; though it is instructive to note that much insight into the physics of the plant may be obtained by a careful study of Boehm's, and especially Hartig's, views, and the various criticisms of them. We may, however, summarise Elfving's remarks, and the chief points for criticism in all the views, as follows.

In advocating the "imbibition theory," no proof is afforded that the lumina of the elements of the living wood are ever *entirely* devoid of water: some water is always present at least in the cells. This does not go against either theory; but the proof that the cells were at any time entirely devoid of water would decidedly support the "imbibition theory."

Enough has already been said as to why we may reject the theory of atmospheric pressure.

Confining our attention to the wood of Conifers, for obvious reasons, the chief facts are as follows. As the young wood-cells lose their protoplasm, water, containing air in solution, occupies the cavity, and bubbles of air are formed alternating with drops of water—in fact, a series of "*chapelets de Jamin*" are formed; only, instead of being simple and in one long tube, each one is complex, and the broken water-columns are confined in closed chambers permeable (to water, but not to air) at the bordered pits, and therefore communicating. One advantage of this is that the "*chapelets*" are less easily broken.

Elfving then passes on to show that, according to Jamin's researches, these columns of water may be of any height likely to come under our consideration: we have thus no more difficulty as to the *suspension* of the continuous columns of water—continuous, that is, in a serpentine course. The molecules of water can pass between the supporting bubbles of air as if they had no weight, since it is only the movement of the masses of water as a whole in the longitudinal direction which is prevented by the capillary forces in the "*chapelet de Jamin*"; the individual particles of water have perfect freedom of motion, and will of course travel towards the transpiration surfaces.

Elfving then goes on to show that many other facts are explained by his theory, and especially the loss of conductivity for water in branches cut off in the air. We must refer the reader to the original paper, however, for further details.

In conclusion, while there is no doubt that Sachs's ingenious "imbibition theory" of the ascent of the water in plants was startling, on account of the bold assumption of the peculiar condition of the water in the cell-walls, it must not be forgotten that it was suggested after a series of profound researches into the properties of wood, and by a master-mind which had tried all previous explanations and found them wanting; moreover, the strangeness of an hypothesis is in itself no argument, and so long as the "imbibition theory" explains more facts than any other it must be accepted on those terms.

If, however, the theory proposed by Elfving turns out to explain the same number of facts equally well, it will have to be allowed that it rests on a foundation of a very different nature, and which can be experimentally tested. It is not easy to suggest a distinctive name for the latter theory; perhaps it might be known as the "step" theory, since the intra-cellular movement of the water up to the leaves seems to be somewhat of the nature of a series of ascents by steps, or from side to side. We recommend the subject to the careful consideration of those physicists who have an adequate knowledge of the structure of plants.

NATURAL SCIENCE IN TASMANIA

ALTHOUGH the scientific energy of Tasmania is not all that could be wished for, still the Royal Society of Tasmania is doing something to keep the flame alive. It is much to be wished that some of its hundred Fellows would devote themselves to an investigation of the flora and fauna of their districts, about which there is still much to be learnt. The *Proceedings* of the Royal Society for 1882 and 1883 have just reached us. The volume for 1882 contains over 180 pages, and is illustrated by four creditably executed lithographic plates. The details of the proceedings at the monthly meetings of the Society are first given, then follow the papers, the more important of which are as follows:—On the fishes of Tasmania, with a classified catalogue of the hitherto recorded species, by Robert M. Johnston. Incidentally he mentions that out of a population of 120,000 persons, it is estimated that about 1050 persons are directly dependent upon the capture and sale of fish. Hobart is the chief centre of the industry. Out of the 188 known species, about one-third are regarded as good edible fish, though only some 21 of these are sufficiently abundant to be ranked as of importance from a food point of view, and of these, some, like the sprat and anchovy, are quite neglected, from want of knowledge and want of energy. Among the so-called fresh-water fish, *Lates colonorum*, though a well-known fish in Australian waters, is confined, so far as is yet known, in Tasmania to one small river discharging into Anson's Lagoon, on the north-east of the island. Though not a sea-going fish, it is chiefly to be found at the mouth of small streams whose connection with the sea is frequently closed by shifting sand-bars; and possibly in this way it became originally acclimatised to fresh water. The fresh-water herring (*Prototroctes maræna*) is said to be the finest of the native fresh-water fishes; chiefly insect-feeders, they give the angler some sport. Some fourteen years ago they suddenly almost disappeared

from most of the rivers where formerly they had abounded, and thousands were seen floating dead down the stream, destroyed apparently by some species of Saprolegnia. It is satisfactory to note that of introduced fish the colonists have now a fine non-migratory trout (brown trout) and a splendid sea-going migratory salmon, the exact species of which is still involved in uncertainty. Among marine fishes special mention is made of the Barracouta (*Thyrsites atun*) and Kingfish (*Th. solandri*), which abound all the year round; but there would appear to be next to no attempt to cure the fish for the foreign market. Mr. R. Etheridge contributes a paper on Trilobites and other fossils from the Lower Silurian rocks of the Mersey River district, Tasmania. Several new species are described, and the species of Trilobites and Brachiopods are figured. Lieut. Beddome describes sixteen new species of Tasmanian shells, and Messrs. Higgins and Petterd some new species of Antechini and Muridæ.

The volume for 1883 contains 65 pages and but few memoirs. Messrs. Higgins and Petterd describe in it some new Tasmanian mice, and the same authors contribute an interesting account of a new cave-inhabiting spider. This species (*Theridion troglodytes*) was found in a recently-discovered cave in the Chudleigh district. The cave was found to consist of several chambers, in the innermost of which the spiders were found. The floor of the cave is about thirty feet below the level of the present entrance, and is only reached by two well-like descents of from fourteen to sixteen feet each, connected by low passages. There was also found a large deposit of mammalian remains, some in the crevices of the rocks, others embedded in the earthy and stalagmitic floor. These remains can be all referred to non-carnivorous marsupials and mice. It is strange that no insects were found, but the cave would seem to be worth a more detailed investigation, which the authors promise, adding that the stalactites surpassed in beauty those of the well-known Chudleigh Caves.

EXPLORATIONS IN ICELAND

THE LAVA DESERT OF ÓDÁÐAHRAUN

IN about the central region of Iceland, on the northern skirts of Vatnajökull, the largest glacier in Europe, is situated the most extensive occidental lava desert, the Ódáðahraun, covering a total area of about 16,000 square miles English. The whole of this wilderness is almost entirely one barren mass of lava, though here and there the traveller may observe patches filled with drifts of sand giving growth to some few stray tufts of upright lymegrass (*Elymus arenarius*); but frequently a journey may be made through this region for days together without one single blade of grass being sighted. The total absence of vegetation and water in these tracts makes travelling here excessively arduous and risky, and these difficulties are still more aggravated by the elevation of the country above the level of the sea, in consequence of which it may frequently happen, even in the midst of summer, that the traveller is enveloped in blinding snowstorms, which preclude all attempts at further progress while they last. In such predicaments no reliance can be placed on the compass, because of iron entering so very largely into the composition of the lava-masses. Hence this desert has hitherto remained a *terra incognita*, and has never been surveyed; yet volcanoes of gigantic dimensions are found here, and many natural phenomena beside, which command great scientific interest. Not only to the world of science has Ódáðahraun been an unknown region, but even the inhabitants of the surrounding country-side have at all times entertained the most vague and ignorant ideas concerning it. For ages they pictured it to themselves as the home of trolls and mountain sprites. Even as late as the present century it was commonly believed that up among the volcanoes there were to be found verdant valleys containing a whole population of outlaws; a belief which took its rise and received its fortification from the fact that jets of steam issuing from the crevassed mountains were taken by distant beholders for smoke ascending from the chimneys of the abodes of outlaws. The outlaws themselves were pictured to the imagination as either human beings of a savage type, or as some preter-human race of gigantic strength. So firmly ingrained in the people was this belief, that even as late as 1830 an armed expedition was despatched from Mývatn for the purpose of exploring the haunts of these communities of outlaws, the result of which, I need not say, proved discouraging.

In ancient times one of the highways of the country ran across the northern portion of Ódáðahraun, which early records show the bishops of Skálholt to have been in the habit of taking on their visitation tours to the east country. This road was used for the last time in 1736, but has been lost since, and now no one is able to point out its locality and direction. Across the southern portion of the lava no attempt at forcing a passage had ever been made by man until a certain adventurer named Pjetur Brynjúlfsson, in 1794, succeeded in threading his way from the East Fjörds westward between the lava and the northern spurs of Vatnajökull, until he struck the road of Sprengisand, which traverses the country right across from the northland to the southland quarter. In 1838 Björn Gunnlaugsson, the famous constructor of the best map of Iceland, undertook a journey of exploration to Ódáðahraun, but fell in with such tempestuous weather that all his attempts at exploration were defeated, and he himself barely escaped with his life. Next year he repeated his journey, and, being favoured with better weather, he forced his way from the south up into the boundary line between the lava and the glacier, and pushed on some distance to the eastward. In this trip he attained some positive results. In 1840 a Danish naturalist, Schythe, intending to explore this region, took the same route, but was overtaken by such excessively stormy weather that, after having lost most of his horses, he just escaped with extreme difficulty into the country-side of Jökuldal in the east country. From this time no attempt at reconnoitring this wild country was hazarded until the stupendous explosion from Askja in 1875 gave such surprising evidence of the enormous activity of the volcanoes in these wildernesses. This year Mr. Watts made his way right across Vatnajökul, striking Askja in his descent over its northern spurs. Shortly afterwards Askja was visited by an Icelander, Jón Thorkelsson, who made his way up to it on foot in the midst of winter. In the summer of 1876 the Danish Government despatched Prof. Johnstrup with a party of scientific men to these volcanic wastes, who explored the region of Askja and constructed a map of the volcanoes. Prof. Johnstrup's is the only scientific exploration that ever yet was carried out in Ódáðahraun. At more recent dates Askja has been visited by several English tourists, such as Messrs. Lock, Coles, and Morgan. In 1880 several farmers from the districts of Mývatn and Barðardal made the complete circuit of Ódáðahraun. But, in spite of all such reconnoitring trips, the whole of Ódáðahraun is practically unknown yet, with the exception of the corner occupied by Askja.

Instructed by the Government, I have now for several years been engaged in surveying the upland tracts of Iceland, exploring the country geographically, and examining into its geological structure and character generally. This summer I resolved to attempt an exploration of Ódáðahraun with such means as I had at my command. With a view to more expeditiously effecting my purpose, I adopted the plan of selecting certain fixed stations on grassy spots here and there about the wildernesses which

surround the lava (the Ódáðahraun), and from each of these in turn, as my base of operations, to undertake trips into and about the lava to such a distance as circumstances in each particular case seemed to warrant. To attempt any comprehensive survey of the whole lava at once, the explorer must be supplied with a far larger stock of ponies than I, with my limited means, could muster, and unless such an expedition can carry sufficient fodder for the animals, any lengthened sojourn in one and the same spot is out of the question. But, by the method of exploration that circumstances forced me to adopt, the result must always come short of one's aspirations.

During the first part of July, which I spent in the country-side of Mývatn, I was engaged in examining the volcanoes of the neighbourhood, which for the most part as yet are quite unknown. I also investigated the geology of the country generally, made collections of insects and plants, and ascended the highest mountain peaks in order both to take the bearings of the mountains about Ódáðahraun, which are visible from Mývatn, and to connect my surveys with such points in the neighbourhood as Björn Gunnlaugsson had formerly fixed trigonometrically. Having finished my outfit and other preparations, I started on July 16, from the place where I am now writing, for the desert. The weather was cold and threatening, with snow-showers travelling along the higher mountain rises. Our first day's eastward march took us over the mountain called Námafjall into the large wilderness of Mývatnsöræfi, which is bounded on the east by Jökulsá í Axarfirði, the longest river in Iceland. Generally speaking this wilderness is covered with old lavas, which are connected with that of Ódáðahraun; but plains of drift-sand open here and there, which are studded with hillocks sustaining tufts of *Elymus arenarius*. In these wilds are found a great number of craters arranged in rows on defined lines from north to south, many crevasses, and rifts floored with earth at the bottom (jarðföll, *i.e.* earth-falls, sinks, or dips), which is but what might be expected, where so many lavas have welled forth from the disruptured bowels of the earth. In this locality there occurred a great eruption in 1875, and in shaping our course to the more southern localities, which were the object of my exploration, we passed close under the northern skirts of the new lava which that eruption created. As the day wore on, a gale of wind arose, and in such a case travelling over these parts ceases to be a pleasure. For some time we had the sand-storm at some distance to the northward before our eyes until it overtook us at last; columnal clouds of brown ashes are whirled into the air, and on joining together in ever increasing numbers the whole view soon becomes enveloped in such dusty darkness that eyesight becomes of little avail; eyes, nostrils, ears are filled with pulverised sand, which is of such a fineness as to penetrate without difficulty even the traveller's clothes; drifts of it find their way into the boxes, and gather together under the saddles and the packing gear on the horses: when in contact with the skin it causes great irritation and general discomfort to the body.

As we proceeded through this wilderness, we were struck by the frequent occurrence of horses' bones, in some cases singly, in others in masses, peeping through the sand between the hillocks. This day, by 11 o'clock at night, we halted in Fjallagjá, a long glen between two rifts, where we found *Elymus arenarius* growing in considerable quantity, but no water; it was a troublesome task to secure our tent in the loose drift-sand, but after repeated attempts we succeeded at last in fixing the pegs tolerably securely in the flanks of the hummocks among the interwoven tissues of the roots of the upright lyme-grass. In the evening the temperature fell to 30°·2 F., and during the night the earth was covered white with snow; our ponies spent the uncomfortable time in constant attempts at running away, which, however, were frustrated by our vigilance. The following morning the same weather continued, still alternating all through the day between sand-storms, snow-showers, hail and sleet squalls. With our view obscured so that we could not take any bearings of the mountains, we still pushed on all day long in a southerly direction, reaching our baiting-place to the south of Herðubreið late at night, in some grass plots along the River Lindaá, a tributary to the above-mentioned Jökulsá, which it joins close on the northern spurs of Herðubreið. The evening came on bitterly cold, and with such a thick fog that even the mountain of Herðubreið in our close neighbourhood was rendered invisible. From this spot, where I remained for a fortnight, I directed my excursions in various directions about the eastern portion of Ódáðahraun. Herðubreið is one of the highest mountains in Iceland (5290 feet), and of remarkably commanding aspect, terminating, towards the top, in a shoulder of precipitous rocks capped with a cone of perennial ice. This mountain, in spite of repeated attempts, has never yet been ascended. In a north-westerly direction from Herðubreið there arises a mountain-range of considerable length, on a line from south to north, which is called Herðubreiðarfjöll or Dyngjufjöll ytri (the outer, *i.e.* northern, Dyngjufjöll), and is utterly unknown. My first excursions I directed to the examination of these mountains. To the south of this range there rises a great volcano called Dyngja, built up of layers of lava with an inclination of 8° to 9° on all sides and rising shield-fashioned to an elevation of 3600 feet; it bears a close resemblance to the famous volcano Skjaldbreið in the south. On the 19th I set out to examine this volcano. Starting in the early morning from my tent on the banks of Lindaá, I had to traverse a lava plateau 1500 feet above the level of the sea, and such was the difficulty of travelling here, that frequently we were on the point of giving up all further attempts at pushing our ponies on, but by dint of perseverance we reached the volcano after a tortuous scramble of four hours and a half. The layers of lava forming the slopes of this volcano are excessively rough and of peculiar formation, all split up into fissures from north to south or hollowed out by caves and lava bubbles. Wherever the foot is planted the ground sounds hollow; in every direction there are innumerable hornitos, seemingly formed originally of a variety of strands of the fiery ooze twisted into all sorts of fantastic shapes, the outer surface suggestive of a tangle of intertwisted snakes of inordinate thickness. When we had made the ascent half way up the mountain, we were overtaken by fog and snowstorm, so that in a short time all objects were hidden out of view and the earth covered with snow. Still in the expectation of the fog clearing away, and the snowstorm blowing over, we went on, and after two hours' brisk walk reached the summit of the volcano. Here all was covered with ice and snow in a temperature of 28° F. Although the blinding snowstorm prevented anything being seen, I set my theodolite on the chance of the darkness clearing, and had to wait for an hour and a half shivering in the biting blast, when the weather so far cleared that I could take the bearings of several surrounding mountain peaks. This volcano has never been ascended by any man before me, nor would the fact have been passed over in silence, if such had been the case, for even in Iceland the activity of fire has hardly left any traces behind comparable to what is witnessed here. The original crater is 1500 to 1600 feet in diameter, and has, some time subsequent to its first formation, been filled with masses of lava, and now exhibits in the centre a large patch of lava round the circumference of which there stand twelve peak-formed lava columns. In the centre of this plain again there is an enormous crater 400 to 500 feet in diameter and 600 to 700 feet deep. It is hardly possible to picture to the imagination any sight more stupendous than that which

opens to view by looking over the verge of this crater down into the precipitous abyss. The crater, with its bottom covered with snow and the sides all whitened with a glacial crust, suggests to the beholder a gigantic cauldron hollowed out in marble. Enormous rocks, which have tumbled down from the brim of the crater, look like minute black specks against the whiteness of the bottom. The composition of the lava is practically entirely basaltic; but reddish rocks of trachyte are strewn about the circumference of the original crater, which shows that sometimes trachytic eruptions have taken place here, as in Askja in 1875. When the weather cleared, I had distinctly in view the greater part of Ódáðahraun as well as Dyngjufjöll proper, and all the lava currents which have taken their course from the latter complex of volcanoes. In a north-westerly direction from the above-described volcano is another, lower, but quite as wide in circumference, to which we gave the name of Kerlingar-Dyngja. Having surveyed Dyngja, we returned the same way we had come, and reached our tent at half-past two o'clock the next morning.

In a southerly direction from Herðubreið there extends a very considerable mountain range, 3400 feet high, which is called Tögl (Tails); it is separated from Herðubreið by a narrow gate through which, once upon a time, a lava current has found its way. Thus Herðubreið is surrounded by lava on all sides, though that mountain itself is no volcano, but a pile of coarse palagonite breccia interspersed with stray thin layers of basalt throughout its lower parts. One of my excursions I directed to the Tögl. From the tops of these mountains an extensive view opens southward over the sands along the course of Jökulsá and the northern region of Vatnajökull. The aspect of the country to the south of Herðubreið is truly forbidding, all covered with the yellow-gray scoriæ from the explosion of Askja in 1875, generally one to two feet in thickness, and no sign anywhere of vegetation. The whole southern horizon exhibits the vast expanse of the snow-white glacial bolsters of Vatnajökull, out of which, in a northerly direction, rises the enormous complex of volcanoes called Kverkfjöll. In some fiery convulsion this mass of mountains has split from end to end, and through the rent a glacier has found its way right down to the level land below. To the west of this rent I observed in the jökull a mass of craters, from one of which huge clouds of white steam ascended into the air. Nothing is known about the volcanic activity in this spot, no one having ever visited those parts of Vatnajökull. On the western side of Kverkfjöll the jökull is one flat ice plateau all the way down to Ódáðahraun, skirting into a number of moving glaciers terminating in sands and extensive moraines, from which flow innumerable affluents to Jökulsá in Axarfjörd. Towards the east, about the approaches to Sandfell, the next highest mountain in Iceland (5800 feet), the jökull exhibits sharp-cut black vertical walls, probably ledges of underlying basaltic belts; but further to the west the flatness of the jökull owes its formation to the substratum being made up of palagonite tufa, a softer and more easily ground material. Our western view was determined by a part of Ódáðahraun, southern Dyngjufjöll, Askja, and the southern parts of Herðubreiðarfjöll. At the southern termination of Dyngja there rises a very peculiarly formed tufa "fell," along the crest of which is to be observed a row of a number of vertical tufa peaks, each from one to two hundred feet high, so that the outline of the mountain gives the impression of a gigantic hedgehog.

Next day I set out on the examination of Herðubreiðarfjöll. Directing our course to the north-east, we ascended on our way a mountain by the banks of Jökulsá called Ferjufjall, near which, as the story goes, there was a ferry in those olden times, when the bishops were in the habit of taking that road over the northern skirts of Ódáðahraun, to which I have alluded already. In a north-westerly direction from this place excessively ancient lavas come to view, which are clearly older even than the Glacial period, exhibiting everywhere large and unmistakable signs of glacial abrasions. In this excursion we came upon a row of those beacons which by general custom in Iceland are erected to point out where roads run through wildernesses. Most of these beacons were but cumuli of stones; one, however, we found still standing, covered with moss and lichens. This we knew now must be the eastern end of the long-lost road, an assumption which subsequent discovery corroborated. As we approached nearer to Herðubreiðarfjöll we came upon a series of craters surrounded by a recent lava, and so rough that no horse might cross it, almost impassable even for a traveller on foot. Leaving our ponies behind, we made our way across this lava, however, as best we could, and reached the highest crest of the mountains shortly before sunset, and enjoyed from it an extensive view. All about these mountains, which are composed of palagonite breccia, there is a number of ridges observable, with small dales and narrow dips scooped out between them, all, however, totally barren of vegetation. About the central portion this range sinks down into low necks honeycombed with many large craters, from which floods of lava have spread over the surrounding country on both sides, east and west, covering an area of some tens of square miles. Having completed my survey of this region, we returned and joined our ponies shortly after midnight, all scratched and lacerated from the lava, with our shoes and stockings in shreds.

TH. THORODDSEN

Reykjahlíð, near Mývatn, August 4

(To be continued.)

THE CONNECTION BETWEEN CHINESE MUSIC, WEIGHTS, AND MEASURES

CHINESE music can now be heard by all who desire to hear it at the Health Exhibition, and more may be learned on the subject from the pamphlet published by the Commissioners for the Chinese department. A curious account of the common origin of Chinese weights, measures, and musical notes is contained in a paper read some years ago before the German Asiatic Society of Japan by Dr. Wagener. The story is based on native legends, and is also to be found among the Jesuit "Mémoires concernant les Chinois." Dr. Wagener says there is not the slightest doubt that the Chinese system of weights and measures is more than 4600 years old; and it is a highly remarkable circumstance that, quite irrespective of the fact that it is more scientific and exact, it possesses all the advantages for which the French metrical system is so much praised. In the first place, it starts from a basis supplied by Nature; secondly, the decimal arrangement is almost consistently employed throughout; thirdly, linear and dry measure proceed directly from the same unit as the measure of weight; and lastly, what the metrical system does not do, it regulates in the simplest manner the relations of musical notes, which latter form the starting-point for the whole system of weights and measures. The following account of the origin of this system (says Dr. Wagener) contains fact and fancy mingled, but it is easy to distinguish between them. In the reign of the Emperor Hoang-ti, who ruled over China in the twenty-seventh century before Christ, the scholar Lyng-lun was commissioned to complete the musical system which had been discovered 250 years earlier, and particularly to lay down fixed rules for making musical instruments. Naturally he had to commence with the bamboo, which had already been long used to give the note for other instruments. He therefore betook himself to the province of Siyung in North-Western China, where, on the northern slope of a range of

high mountains, a species of bamboo grew, which, on account of its uniformity and its structure, being neither too hard nor too soft, was exceedingly suitable for a wind instrument. He cut one down and tried it. Tradition says that it gave the same note as his own voice when he was excited by no emotion; and the rippling of the sources of the great Hoang-ho, or Yellow River, which were in the vicinity, followed in the same tone. At the same time the fabulous bird Fung-Hiang, accompanied by his mate, flew to the place. Both perched themselves on a neighbouring branch, and commenced a song, in the course of which each of the birds gave six separate notes. These are the notes which are called the six male and six female tones in the scale discovered by Lyng-lun, and which correspond to the ancient doctrine of the male and female principles in Nature. As a matter of course, the deepest of the male notes was the one already discovered by the philosopher himself. He now endeavoured to reproduce the other notes with the help of bamboo pipes, and succeeded. His task was now to lay down fixed rules as to the length of the pipes, so that thenceforth they could be easily constructed everywhere. For this reason, and also because such a scale of notes depends upon slight differences of length, and there were scarcely at this time instruments to divide great lengths, he necessarily arrived at the notion of passing from the less to the greater, and of laying down an adequately small natural unit for his measurements. That could be nothing else but a grain of seed; and now the point was to get seeds of the greatest possible uniformity. He chose a sort of millet, the *Sorghum rubrum*, the seed of which is of a dark brown colour, and which is said to possess the advantages of greater hardness and uniformity than that of the gray and other kinds. The seed is pointed at the ends, and from one point to the other the length is somewhat greater than in the direction at right angles. Lyng-lun now fixed the length of the pipe, which gave the keynote at 81 grains of the seed placed lengthwise in a row. But when the grains were placed breadthwise it took 100 grains to give the same length. Thus the double division of 9×9 and 10×10 was naturally arrived at. According to the dimension in question, it was called a musical or an ordinary foot, the latter being introduced with the decimal subdivision as a measure of length. The breadth of a grain of seed was 1 *fen* (a line), 10 *fen* = 1 *tsun* (an inch), 10 *tsun* = 1 *che* (a foot), 10 *che* = 1 *chang*, 10 *chang* = 1 *ny*. In subsequent times the line was divided into tenths, hundredths, &c. Lyng-lun also laid down rules for the breadth as well as for the length of the pipe, because, although the note is essentially dependent on the length, it is nevertheless necessary for its purity that the pipe should be neither too broad nor too narrow. He therefore fixed the circumference on the inside at nine grains laid lengthwise. With these dimensions, namely, a length of eighty-one grains, and an internal circumference of nine, the pipe which gives the keynote contains just 1200 grains, and this volume accordingly was made the unit of dry measure, and was called a *yo*: 2 *yo* = 1 *ko*, 1 *ko* = 1 *cheng*, 10 *cheng* = 1 *ten*, 10 *ten* = 1 *hu*. So far we see how the units of length and dry measure were connected with the musical keynote. The twelve notes of the scale are all derived from the keynote, and are to a certain extent comprehended in it. Hence if the 1200 grains contained in the pipe are divided among the twelve notes it gives to each a hundred, and the weight of these hundred grains was made by Lyng-lun the unit of weight. This was divided and subdivided on the decimal system until a single grain became the lowest weight of all. At a later period even the coinage became connected with this system, for one of the weights, the *leang*, corresponding to our ounce, became the weight of metal put into a coin, so that the modern *tael*, in which mercantile quotations are found every day in the *Times*, is merely an ounce of silver, and is thus directly connected with the musical scale. Finally, says Dr. Wagener, it appears from this account that, in China, weights, measures, coinage, and the tuning of musical instruments have been derived quite consistently from a constant unit supplied by Nature herself, and that the essentials of this system are over 4600 years old.

NOTES

THE Queen has been pleased, through His Grace the Duke of Richmond and Gordon, to intimate a subscription of 25*l*. to the Scottish Marine Station for Scientific Research, Granton, Edinburgh.

THE Washington International Prime Meridian Conference discussed at length on Monday a resolution for adopting the Greenwich meridian, which several American and British delegates advocated. M. Janssen, the French delegate, opposed the motion in a long address, arguing in favour of what he called a "neutral" meridian, and suggesting that the prime meridian should run, either through Behring Straits, or one of the Azores. After some further debate the Conference adjourned subject to the call of the chairman. No opposition to the election of Greenwich was shown excepting by France, but doubts are expressed as to whether the Conference will have any result.

ACCORDING to the *Standard's* Calcutta Correspondent, the Commission under the direction of Dr. Klein, appointed by the Indian Government to examine into the cholera question, is satisfied that Dr. Koch's microbe is not the cause of the disease. The Commission is still continuing its inquiries, but so confident is Dr. Klein on the microbe question that he swallowed a number of them without any evil results.

"THE Philadelphia meeting of the American Association," *Science* states, "is credited with being the most successful up to this time. The total attendance was 1249. Great Britain contributed 303; Pennsylvania, 246; New York, 161; Massachusetts, 87; District of Columbia, 84; New Jersey, 58; Ohio, 57; Connecticut, 32; and Virginia, 22. The membership was increased nearly 25 per cent., 515 new members being elected, the number of members up to this meeting being 2033. The number of papers read was larger than ever before, and it is to be hoped that the weeding-out of the trivial matters so often offered was carried to a greater extent than usual. There was a general feeling that there was too much going on. A large portion of the physicists were engaged as examiners at the Electrical Exhibition, and were, of course, interested in the meetings of the Electrical Conference. Somewhat less science, and somewhat more time to enjoy the junketing, would be more in accordance with the desires of many, if one may judge from the opinions expressed on the way home. A proposition to confine the reading of papers to the mornings would have met with many supporters."

IT would seem that the International Scientific Association, which it was proposed at Philadelphia to organise, has been really founded. *Science* informs us that it has now a more assured existence, thanks to the fund of twenty thousand dollars which will be established through the liberality of Mrs. Elizabeth Thompson. Of this fund five thousand dollars have already been paid to the Association, and five thousand more will be paid next year on condition of ten thousand being raised from other sources. The income from this fund is to be devoted to research. Not only did Mrs. Thompson give liberally to this new Society, but she also gave one thousand dollars to the American Association for the Advancement of Science, to be used in researches on light and heat. Mrs. Thompson takes great interest in the recent marvellous advances in the application of electricity, and felt a desire to contribute, as far as lay in

her power, to the advancement of our knowledge of the forces of Nature. Appreciating the unity of energy, whether displayed as heat or light or electricity, Mrs. Thompson gave the money for researches as to the nature and sources of light and heat, in the hope that more may be learned of the connection which may exist between heat and light and electricity.

PROF. COSSAR EWART has sailed for the United States on a semi-official mission connected with the Fishery Board. He is to make full inquiry into the fishery regulations of the United States, to examine the fish hatcheries there, and otherwise to gather all possible information on the subject upon which he was engaged at home during last winter and spring with so much energy and success.

THE death is announced of Dr. Leopold Fitzinger, formerly custodian of the Zoological Court Cabinet at Vienna.

THE latest news from the Lena Meteorological Station at Sagastyr appeared in the last issue of the St. Petersburg *Izvestia*, dated January 3 and February 14. The small-pox, brought last year from Yakutsk, has made great ravages among the already scarce population of the delta. Nearly all (seventy) Yakuts living at Bouloun have died from the epidemic; and in the three settlements at Cape Bykoff forty persons died from it; even at Kytakh, close to the Meteorological Station, a Yakut who had fled from small-pox died in December last. The staff of the Observatory were quite well in February, and, with their provisions of fresh meat, were not afraid of scurvy. The magnetic storms were not so strong nor so frequent as last winter. The greatest cold witnessed in December was $-48°$ C., and, on the whole, the winter was far milder than last year. Frosts below $-40°$ were rare, and temperatures as low as $-52°$ were not witnessed this winter. The average temperature of February was only $-33°$, instead of $-41°$, as it was in 1883. On the contrary, strong winds were more frequent than last year.

THE new astronomical Observatory in Hong Kong appears to be now in full working order under Dr. Doberck. We have received its usual monthly weather reports, containing copious observations on the barometric pressure, temperature, temperature of evaporation and radiation, relative humidity and tension of aqueous vapour, duration of sunshine, rainfall, duration and velocity of the wind, &c.,—in all, fifteen tables. The meteorological work, especially when taken in connection with that of the Observatories at Siccawei, Manilla, and Tokio, and the observations at the various Chinese Customs stations and lighthouses must be of great value. For the benefit of shipmasters the Astronomer publishes daily a *China Coast Meteorological Register*, giving a summary of the atmospheric circumstances along the coast of China.

AT the same time as the German Association the German Meteorological Society met at Magdeburg and held a public meeting on September 20. Prof. Neumayer spoke on the development of meteorology and its importance in the life of nations. The following gentlemen were elected honorary members of the Society:—Profs. Buys-Ballot (Utrecht), W. Farrel (Washington), J. Hann (Vienna), G. Mohn (Christiania), A. Mühry (Göttingen), and E. E. Schmid (Jena).

PHYLLOXERA has made its appearance in the Pomological Institute of Proskau (Silesia). It is hoped, however, that the spread of the disease may yet be prevented.

THE Russian University of Kief has elected Profs. Kolbe, Helmholtz, Kirchhoff, Pettenkofer, and Hoppe Seyler as honorary members.

A COMMITTEE has been formed at Lucerne with a view of erecting what is called a "universal column." It is to measure 300 feet in height, and is to contain in its interior relief portraits of all the celebrated men and women of the present era on bronze tablets. Another project of the Committee is the building of a "museum of the nineteenth century," to be dedicated to art, science, inventions, commerce, and industry, and to contain the busts and statues of all distinguished persons in these domains. The cost is estimated at seven to eight million francs (280,000*l.* to 320,000*l.*), and is to be met by subscription, lotteries, &c.

THE old lighthouse erected by Smeaton upon the Eddystone rocks 125 years ago, recently replaced by a new lighthouse, has been re-erected upon the Plymouth Hoe. It was opened on September 24 with appropriate ceremony.

PROFESSORS and teachers of mechanics and mechanical engineering have the greatest difficulty in getting suitable models to illustrate the different machines, and combinations of parts, under discussion in their classes; diagrams go a long way as a means of illustration, but appear sometimes very complicated, more especially when the paths of the moving parts are drawn. Take, for instance, the link motion of the locomotive, —the diagram of the motion showing the relative positions of the different parts, when one of the cranks is placed in eight different positions in its path, is very complicated; when a model is used all this vanishes, the action being very simple, and perfectly plain to the average student. Then again the various arrangements of spur-driving gear, nest-gearing, and similar appliances, are very soon understood when illustrated with a model; with a diagram, or drawn on a blackboard, they look complicated and confusing. Perhaps the best and simplest form of demonstrating mechanics is by means of scale models, saving the teacher many long descriptions, and giving the student at once the best possible opportunity of understanding the construction as well as the motion of the different parts. We have before us an Illustrated Catalogue of Apparatus for Technical Instruction, &c. (manufactured by James Rigg, engineer, Queen Victoria Street), issued to meet the demand for appliances required in the various branches of technical education. The grouping of the several subjects is similar to that adopted by the Science and Art Department, the corresponding number of the Government list of 1883 is given side by side with the catalogue number, and the selection of models is decidedly good. The index includes all the subjects generally taught in technical classes. The models are constructed to secure strength and durability, without unnecessary finish, thus placing before the public a valuable series of models for the advancement of technical education at a moderate cost.

THE Japanese Government nominated Mr. Kikuchi Dairoku to attend the Meridian Congress at Washington. This gentleman is a Cambridge Wrangler, and at present fills the Chair of Mathematics at the Tokio University. It says not a little for the scientific advance of the Japanese that they can find one of themselves qualified to represent them at such a scientific meeting as that now being held at Washington.

WE have received from the Commissioner for Japan to the Health Exhibition a catalogue, with explanatory notes, of the exhibits of the Japanese Education Department now at South Kensington. It is not, we believe, generally known that the Japanese section was intended to have been much larger, and the articles were actually shipped from Japan; but owing to a fire on board the steamer by which they were being conveyed, they were spoiled. The loss was chiefly among the appliances, designs, &c., relating to art education, silk-weaving and embroidery by girls at the industrial schools, and specimens of work in bronze by the deaf-and-dumb. The pamphlet before us is much more than a bare catalogue; it is much more a long series of notes on Japanese education and educational appliances past and present, those dealing with the past being by far the

more interesting. On p. 27 we notice a curious statement. No. 61 to No. 85, says the catalogue, are works published by the University of Tokio. "As English translations accompany many of them, the visitor will be able to gather at once what they treat of," in other words, it is implied that the works were originally written in Japanese, and were afterwards translated into English. This is wholly incorrect; the works which are spoken of as "translations" are the originals, and were written by European gentlemen (whose names, by the way, are suppressed) in the educational department of Japan. Most of them were noticed at the times of their appearance in our own columns. They are all works of high scientific value, and their publication reflects much credit on the University, but, if any remark were necessary at all, it should have been that the Japanese was the translation, and the English the original, and not as stated in the catalogue. Exhibits 86 to 103 are the theses of the students in chemistry presented on graduation, and here the writer's name is in every case given. These papers are no doubt creditable in their way; still they are only the ordinary work of good students, while the others approach in many cases to the dignity of considerable volumes, and represent much labour and knowledge. Yet here the authors' names are withheld, and they are actually spoken of as translations. The writers were men whose names will long be connected with Japanese educational advancement—Messrs. Morse, Knipping, Korschelt, Ewing, and others—and the Commissioner can hardly have been ashamed to have their names in his catalogue, for all who know anything of Japanese education know how much science in Japan is indebted to the labours of these and others like them. Probably quite unintentionally there is not only the *suppressio veri* but also the *suggestio falsi* in the catalogue under this head.

AT the Working Women's College the opening address for the year to students and friends will be delivered in the Maurice Hall of the College, 7, Fitzroy Street, W., to-morrow (Friday) night at 8 p.m., by Mr. George Macdonald. Those interested in the work of the College are invited to be present.

MESSRS. LONGMANS AND CO. announce the following publications as forthcoming:—"Louis Pasteur, his Life and Labours," by his Son-in-Law; translated from the French by Lady Claud Hamilton. "The Science of Agriculture," by F. J. Lloyd. "Custom and Myth; Studies of Early Usage and Belief," by Andrew Lang, M.A. "A Manual of Telegraphy," by William Williams, Permanent Assistant to the Director-General of Telegraphs in India. "Above the Snow Line: Mountaineering Sketches between 1870 and 1880," by Clinton Dent, Vice-President of the Alpine Club.

WE have to record the death of M. Bourdon, the inventor of the metallic barometer and manometer which are so largely used.

IN the report last week of the paper read by Prof. Ramsay and Mr. Sydney Young before the Chemical Section of the British Association, "On Evaporation and Dissociation" (p. 551), in the sentence "as the dissociation *increases* the curves approach, &c.," "increases" should be "decreases." In Mr. Nicols's letter on "Salmon-Breeding" (September 25, p. 513, col. 1, line 13 from top), *parrs* should be *pairs*.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista* ♂) from West Africa, presented by Miss Ethel A. Hutton; a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Mr. W. Phillips; two Great Bats (*Vespertilio noctula*), British, presented by Capt. W. St. George Ord; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Mrs. S. Russell; an Erxleben's Monkey (*Cercopithecus erxlebeni* ♀) from West Africa, a Common Marmoset (*Hapale jacchus*), a Black-eared Marmoset (*Hapale penicillata*) from South-East Brazil, a Pig-tailed Monkey (*Macacus nemestrinus* ♀) from Java, two Small Hill-Mynahs (*Gracula religiosa*) from Southern India, a Blue-bearded Jay (*Cyanocorax cyanopogon*) from Para, an Alligator (*Alligator mississippiensis*) from the Mississippi, deposited.

PHYSICAL NOTES

M. GARBE has laid down the two following laws in connection with Lipmann's capillary electrometer:—(1) The capillarity constant of mercury is greatest when the electrical difference at the meniscus is *nil*, and, as a rule, its value is independent of the sign of this difference. (2) The electrical capacity at a constant surface of an electrode plunged in a liquid is purely a function of the electrical difference, independent of the sign of that difference, and is least when that difference is *nil*.

M. BEETZ has made a standard cell which is a modified form of Latimer Clark's mercurous sulphate cell. It consists of a tube in which a compressed cake of mercurous and zincic sulphates is placed; at one end of the cake the zinc pole is placed, and at the other end the mercury pole. On short-circuiting the following results were obtained:—

5 minutes ...	1·440 volts	6 hours ...	1·437 volts
1 hour	1·439 ,,	12 ,, ...	1·434 ,,
4 hours ...	1·439 ,,	48 ,, ...	1·408 ,,

The resistance was 15·700 ohms.

M. DECHARME has made some experiments comparing a drop of water falling on to a surface of glass, which he had covered with a thin layer of minium so as to preserve forms obtained, with a rifle bullet striking a target. He found a striking analogy in the results.

M. FOUSSEREAU has found the specific resistance of distilled water, in the same apparatus, to vary from 118,900 to 712,500 ohms, that is to say, in the ratio of 1 to 6. He accounts for this in three ways: (1) by the solution of the surface of the containing vessel; (2) by the solution of matter from the air; (3) to the effect of the dissolved matter during distillation. On the first point he found that at 15° C. after standing in a glass vessel for forty eight hours the resistance fell 1/30. At 30° C. the change was more rapid, and at 75° C. the resistance varied, so that he was unable to make any measurements. The solution of gases from the air had only a small effect. On the third point great care was observed. Experiment proved that the addition of 1/1,000,000 of potassium chloride reduced the resistance 1/3; according to M. Bouty, hydrochloric acid is five or six times as powerful. In respect to ice, M. Foussereau found that at the moment of congelation the resistance increased nearly 15,000 times, and continued to increase as the temperature fell. Thus ice at −1° C. has a specific resistance of 4865 megohms, and at −17° C. 53,540 megohms. A sample of ordinary water gave 65 times the conducting power, whilst the ice from it was from 30 to 40 times as conducting.

HERR WARBURG has succeeded in electrolysing glass; the method that he adopted is as follows:—He heated a piece of soda lime glass to about 300° C.—at which temperature it is a conductor—and placed it between mercury electrodes. It was necessary to use from 15 to 30 Bunsen cells for a long period. He then found that at the anode side of the glass he had a layer of silicic acid; this layer very quickly reduces the strength of the current owing to its bad conductivity.

M. DUTER has made some very interesting experiments on magnetic shells. He finds that, if thin disks of steel be placed in the field of a powerful electro-magnet so as to magnetise them through from face to face, when they are removed from the field, they have almost entirely ceased to be magnets; but the faint trace left still showing that the disks were magnetised as shells. Again, M. Duter built up a series of steel disks, either separated by thin paper or cardboard, or placed directly together. This series was then magnetised with the disks in the same position as before: now on removing the whole from the field he found he had a permanent magnet, fairly powerful and regularly magnetised. His next step was to take the magnet to pieces by separating it disk from disk; each disk was then found to have almost ceased to be a magnet, but on placing them together again he found that he still had a permanent magnet, but weaker than before.

M. BOUQUET DE LA GRYE has invented a multiplying seismograph. The instrument has been fixed at Puebla, and a series of observations made during November and December 1882 show twenty-two abnormal movements in one month, probably seismic, only one being felt at Puebla. The sun and moon have been proved to have a direct action on the pendulum, the sun repelling it and the moon attracting it.

M. A. RIGHI has published a paper in the *Journal de Physique* on "The Influence of Heat and Magnetism on the Electrical Resistance of Bismuth." He says that the resistance of bismuth increases between some temperatures and decreases between others. These variations can be drawn in a curve which shows a maximum at a low temperature, then a minimum, again another maximum just before fusing, and a second minimum whilst in a liquid state, this minimum being in value about one-half the foregoing maximum. The positions of these maxima and minima vary with the physical conditions of the bismuth; if the bismuth be cooled rapidly, the two maxima approach one another until they even merge together, and the curve becomes similar to a parabola. In the first case the two maxima occur at −40° C. and 240° C., the intervening minimum being at 115° C. In the case of rapidly cooled bismuth the single maximum is at 50° C. These results only occur in commercial bismuth, and are more exaggerated as the bismuth is hardened in the preparation, wire showing them more than castings, and cold drawn wire more than hot. Pure bismuth behaves like an ordinary metal. The resistance of bismuth either pure or commercial is increased in the magnetic field; in some experiments the increase has been one-eighth of the original resistance. The increase in resistances is generally proportional to the magnetic force, and decreases with a rise in temperature.

IN a recent paper by M. Planté, he gives the result of some experiments made to arrive at the cause and explanation of ball lightning; he was led to these experiments by having one of his mica condensers destroyed by a similar phenomenon. He charged one of his condensers from his secondary battery of 800 pairs, when the condenser was pierced, and instead of a bright spark a small incandescent globule was formed, which moved slowly over the surface of the condenser, following the parts where the insulating layer had least resistance, and destroying the metal film; the path being most curious and erratic. This motion continued, and the globule lasted one or two minutes, until the batteries ran down. In the case of a condenser in which the insulating material was ebonite, a sound was emitted similar to a toothed wheel being rapidly rotated against a piece of cardboard or sheet metal; at the same time there was a strong smell similar to that produced when ebonite is burnt. M. Planté repeated this experiment with 1600 secondary cells, which gave an electromotive force of 46,000 volts, and obtained a similar but much more complicated result. The second experiment made was to make a condenser of two flat pads of filter paper moistened with distilled water and brought near together so as to form an air condenser; now on connecting this condenser with his battery he obtained an incandescent globule which moved about between the pads and passed from one to the other. In this case he noticed that if the pads became dry at any point the globule disappeared, but either appeared at some other point, or at the same point again, as soon as it again became damp. In this experiment he found that the globule lasted a much greater time than in the case of the mica condenser, which fact was owing to the greater resistance in the condenser plates which did not allow the battery to discharge so rapidly.

GEOGRAPHICAL NOTES

To the *Bolletino* of the Italian Geographical Society for September Prof. Bellio contributes an account of a curious manuscript by the Sicilian missionary Fra Teramo Castelli (1597–1659), who spent the better part of his life in Transcaucasia. This altogether unique work comprises seven thick folio volumes, originally preserved in the Theatine Convent, Palermo, but, after the suppression of the religious orders, rescued from destruction and removed by P. di Marzo to the communal library of that city. Its peculiar character will be at once evident when it is stated that there is no written text, all the volumes containing nothing but pen-and-ink sketches and other illustrations, accompanied by brief legends or explanations mostly in Italian or indifferent Latin, but occasionally also in Greek and Georgian. This method was deliberately adopted by the author or artist to convey his impression of men and things, because, as he naïvely remarks, "we thus see at a glance the fact, which, if written out, would take up much time both of the writer and of the reader." Of the designs, of which there are altogether 1176, 347 are of little value, being occupied with mystic, devotional, or ascetic subjects. But all the rest are highly interesting, especially to students of geography and ethnography. The two regions chiefly illustrated are Mingrelia (basins of the Rion and Ingur) and Georgia proper (basin of the Kur), jointly stretching from the Euxine to the Caspian, and bounded on the south by Armenia, on the north by "the kingdom of Astacan," that is, the Tatar khanate of Astrakhan. Mingrelia is identified with the ancient Colchis, while Georgia, "quæ Gurgistan barbaris dicitur," is said to comprise not only Iberia, but also a part of Greater Armenia and a portion of Atropatia, or Atropatene. Frequent allusion is made to the great fertility, rank vegetation, and moist climate of the low-lying tracts, whence arise "dropsy, extremely dangerous tertian and quartan fevers, causing worms to abound in the stomach and flesh of the people, on which account they consume vast quantities of salt." They are otherwise describey as Christians of the Greek rite "with a little difference," very numerous and warlike, especially the highlanders, still sometimes wearing armour, and endowed with great physical beauty. There is a portrait of a certain Mamia "Gorielis Princeps Armatus," mounted on a charger, and dressed in a complete coat-of-mail, with high boots, helmet, plume, spear, and shield. It is curious that this practice of wearing armour still lingers among the Khevsur highlanders of the same region. A striking contrast to the Gorelian warrior is presented by the picture of Vonmissa, a poetess wearing a simple robe, a double row of pearls round her neck, a head-dress also fringed with pearls, and a rich mantle lined with fur. She holds a quill in her right hand, a scroll of paper or parchment in her left, and round about are disposed an ink-bottle, more paper, a penknife, a pair of scissors, and a vase apparently containing perfumes. Another lady, the Princess Lipardiani, is provided with a fan somewhat in the shape of a violin, with a little square mirror let in at the narrow part, exactly of the same form as is still fashionable in the country. "According to the seasons they gather the harvests of barley, millet, grapes, and nuts," is a legend occurring under one of the numerous designs representing peasants reaping corn as high as a man and making sheaves such as are commonly seen in Italy. Elsewhere is figured a scene in a market town with the explanation: "Trade is carried on by barter; one hen for two pounds of salt, one sheep for two hens, one sword for two goats, one horse for three oxen," adding that all these values are determined by official tariffs. Amongst the sports is one called *trocus*, which from the accompanying description seems to be identical with the game of polo recently introduced into England from the East. "Four horsemen gallop about playing with a ball the size of an orange, which they endeavour to pick up from the ground, hurl into the air, and drive forward with a racket." Then it is added in Latin: "Equites ludentes hoc pacto ut aspicis rarissimi sciunt se ipsos gerere, requiritur agilitas quædam cum certo determinato impulsu ita ut si plus aut minores ponuntur spiritus non bene ludunt sæpeque quasi novi *fetotontes* cadunt in terra ab altis equis cursoribus." Under several characteristic portraits of natives occur Latin verses pointing out how the mental faculties and moral tendencies may be deduced from the form of the head and expression of the features, thus anticipating the doctrine of Lavater. Of forty-six designs figuring the Sultan and his Court, his army and chief subjects, several are of considerable ethnological interest, comprising portraits of Persians, Arabs, Tatars, Egyptians, Circassians, Indians, Chinese, Portuguese, and other nationalities. Appended to these figures is the, for the times, remarkably liberal sentiment that all nations have good and bad qualities irrespective of their religions, and that the Chinese have a good system of philosophy and theology, although different from that of Christian peoples. Prof. Bellio's paper is enriched with a large number of facsimiles conveying an excellent idea of these curious volumes.

THE two last numbers of the *Russische Revue* contain articles on the little-known peninsula of Kamchatka, its geography, natural resources, and the history of its conquest. The districts adjoining the sea are so mountainous as to be almost uninhabitable. There is, indeed, one magnificent harbour in Awachinska Bay, and on this stands Petropaulovski. A chain of volcanic

mountains, some of them reaching to a height of 5000 feet, runs down the centre of the peninsula, and through this the large navigable river Kamchatka makes its way to the Pacific Ocean. The valley of this river is the most cultivated portion of the district. The hills are covered with forests of fir, larch, cedar, birch, &c., and in these are found numerous wild animals, such as the fur sable, the otter, foxes of all colours, and the bear, which latter, on account of the great supply of food, attacks neither man nor the domestic animals. It is curious to note that the squirrel, which is universal in Siberia, is not found here at all. Swans, wild ducks, &c., are found in great quantities in the lakes and marshes in the interior, and their eggs, as well as the birds themselves, are taken in great numbers by the people. The fish which throng the rivers in enormous numbers in the summer form the principal food of the natives. For the most part they are salmon (*Salmo salar*), and are dried and stored up for the winter; but owing to the scarcity and dearness of salt the fish frequently become rotten, and the people suffer great privation. The rigour of winter is much softened by warm ocean currents, which create those thick continuous fogs that render the coast so dangerous to navigation. The total population of both sexes is put down at only 6500 souls, but owing to the total absence of agriculture, and to the primitive methods adopted for preserving food for the winter, these are frequently in a state of semi-starvation. For all except bare food they have to look abroad—clothes, utensils, tea, tobacco, &c., and all these they purchase by means of their fur sable, which is unequalled in any other part of the world. About 5000 of these skins are sold each year at 15 to 20 roubles each. At the beginning of the present century, cattle were introduced from Yakutsk, and, owing to the excellent grass and water, would have thriven well, but on account of the lack of industry or energy on the part of the natives, it was found impossible to lay in sufficient stores of fodder in winter. The question whether agriculture is possible in the peninsula has never yet been answered. Markets exist in the ports of Eastern Siberia, which are at present supplied with such articles as salt meat, butter, cloth, and hides from San Francisco. The main obstacle to agriculture is the excessively damp and constantly foggy climate. The sun seldom shines, and does not therefore give enough warmth for the growth of rye and wheat. The trade is almost wholly with California; and as there is little or no money there it is carried on by a system of exchange, the natives offering their sable skins in return for such goods as they require. The articles conclude with an historical sketch of the peninsula down to the annexation of the Amoor region to Russia in consequence of the treaty with China of 1860.

THE latest news from Col. Przevalsky communicated to the Russian Geographical Society is dated January 20 and March 22. In the first of his letters the Russian traveller writes from Dynyouan-in, where he was staying at the residence of the Prince of Alashan. After leaving Urga on November 20, he reached this small town in Alashan on January 15, after a journey of 740 miles across the desert of Gobi. The cold in the neighbourhood of Urga was very intense, and the mercury was sometimes frozen; in Alashan it was, on the contrary, quite warm when there was no wind. M. Przevalsky proposed to leave Dynyouan-in the next day, and *viâ* the Tchebsen temple reach Kuku-nor. He wrote his second letter from this place. He had crossed Southern Alashan and the Han-sou Mountains without difficulty. There he spent the month of February, principally in hunting and in zoological explorations, which yielded rich collections. On March 23 he was to leave Tchebsen for Kuku-nor. The Chinese authorities did not hinder his advance, but refused to give him a guide for the sources of the Yellow River (Hoang-ho); the indefatigable traveller did not, however, attach any importance to this refusal, being sure of finding the sources of the Hoang-ho himself. When the Tsaidam was reached, M. Przevalsky proposed to establish his first station there, and to continue his journey with a few men and provisions. His second station would be established at Ghast in Western Tsaidam. As to Thibet, he had decided to go to Lassa if the Thibetians did not oppose him. Otherwise he would explore only Northern Thibet as far as Lob-nor, endeavouring to penetrate as far south as possible.

ANOTHER traveller who has been sent out by the Russian Geographical Society, M. Potanin, wrote on April 17 from Tientsin. The expedition had reached Chefoo on April 13 on board the corvette *Skobeleff*, and continued the journey on [?] Pekin, and there to obtain authorisation for the journey to Ordos and Han-sou *viâ* Utay or Kuku-Koto.

IN a paper contributed to a recent issue of the *Revue de l'Histoire des Religions*, M. Léon de Rosny, the Japanese scholar, argues that one of the two chief chronological factors in the present Japanese race is the Aino. It has long been recognised that there was a certain intermingling of the original Japanese invaders with those whom they drove before them, and who now remain in parts of Yezo, the Kuriles, and Kamchatka; but M. de Rosny thinks that the Aino element is an exceedingly large one, and permeates the whole race. His arguments are based on an examination of the cosmogony described in the earliest works. He finds here two separate and distinctly marked mythologies, one of a transparently aboriginal character. The Japanese of to-day is, he believes, a mixture of the conquering yellow and the conquered white races.

THE Berlin Geographical Society heard a lecture on October 4 from Herr Robert Flegel, who has just returned from making an exploration in the region of the Niger, as agent of the German African Society. Herr Flegel's exploration has occupied the last two years, in the course of which he explored all Adamawa and discovered the sources of the Binuë; but his effort to travel from the Binuë to the Congo ended in failure, owing to the feuds and violence of the intervening tribes. Herr Flegel carried away with him the conviction that the Binuë is navigable for 1100 kilometres, and its chief affluents, as for instance the Taraba, for a distance of from fifty to sixty nautical miles during five or six months of the year. Herr Flegel is accompanied by two natives, who attended him on his travels, and who listened on bended knee and with crossed arms to the praise bestowed upon them by the President of the Geographical Society for their devotion to their master.

NEWS has been received from the leader of the German expedition in South America, Dr. von den Steinen. The expedition had arrived at Aldea dos Bacairis, on the Rio Paranatinga, the ultimate point from which regular communication with the civilised world is possible. Their journey had been considerably delayed by untoward circumstances and difficulties. They left Cuyaba on May 26, and reached Rosario on June 2. There they stayed a few days to purchase provisions. On June 14 they reached the first Aldeamento of the Bacairis on the Rio Novo, a tributary of the Arino. There they remained a week, making anthropological and linguistic investigations. They continued their march on June 21, and arrived at Aldea on the 28th. On July 5 they were to cross the Paranatinga.

A GEOGRAPHICAL SOCIETY is about to be founded in the Scottish capital; it is to be opened next month by Mr. H. M. Stanley.

A GIGANTIC EARTHWORM

IT is well known that earthworms exist in many parts of the world of enormous size compared to those with which we are familiar in this country.

Dr. Templeton mentions (see *Proceedings* of the Zoological Society, 1844, p. 89) large worms which are abundant after heavy showers in many parts of the island; this species, named by him *Megascolex cæruleus*, is represented by a number of examples in the British Museum, some of which are certainly more than two feet long. In South America at least two distinct genera are to be found which attain to a very considerable size. Prof. Perrier, who is so well known as an authority upon the anatomy of the group, has given them the appropriate name of *Anteus* and *Titanus*. Dr. Horst of Leyden, also well known for his researches into the anatomy of earthworms, has published in the "Notes from the Leyden Museum" a description of two species belonging to another genus, *Acanthodrilus*, which measure three feet or so in length; they are natives of Western Africa. Australia and New Zealand are also inhabited by these gigantic creatures. Prof. Thomas, of Auckland, New Zealand, informs me that he has heard of a large earthworm two or three feet in length, which is to be found in the interior of the island, and one of similar size has lately been described from South Australia, by Prof. M'Coy, under the name of *Megascolides*. There is, however, a still larger species which inhabits South Africa. Forty years ago Rapp described

and figured an earthworm six feet two inches in length, which was obtained from the neighbourhood of Port Elizabeth, but since that time there does not appear to have been any further description of the animal. Being anxious to secure a specimen for dissection, I applied to the Rev. G. R. Fisk, who most kindly sent me a living one; it is the same species as that described by Rapp, but is not quite so large; it measured between four and five feet in length, and about half an inch in diameter; these measurements are, however, rather under than over-stated; it is not easy to get an exact idea of the length of the animal, since it expands and contracts within such very wide limits. The general appearance is much like that of the common British species, the bristles being disposed in four series of pairs to each segment; this outward resemblance is not borne out by the internal structure, which is very different from that of *Lumbricus* or any other genus.

These monstrous worms appear to be fairly abundant in the neighbourhood of Port Elizabeth and other parts of the Cape Colony (see the *Cape Times* for May 29, 1884), but are only rarely seen; they do not seem to move about at night like our British worms; only heavy and prolonged rains drive them to the surface from their underground burrows; on such occasions, as I am informed by a correspondent at Kleinpoort, which only take place a few times a year, the ground is often covered by hundreds of these creatures slowly crawling about in all directions; they must present a most remarkable sight; as a general rule they do not return into the earth after the rain has ceased, but remain above ground, and are shortly killed by the sun. The same gentleman states that the soil in which he has observed them is of a hard clayey nature, and retains a considerable amount of water, which is invariably brackish. This fact has some significance in connection with the geographical distribution of earthworms. It was formerly believed that earthworms and their eggs were killed by immersion in salt water, and consequently the presence of similar or closely-allied species in two regions now separated by the sea would be a strong indication of a previous land connection, setting aside, of course, those cases evidently due to man's interference (*i.e.* the importation of earthworms from tropical countries among the roots of plants). The fact that this earthworm from the Cape, and presumably its eggs, are unaffected by brackish water, and still more the occurrence of another genus, *Pontodrilus* (cf. Perrier, *Arch. de Zool. Exp.*, t. ix.), among decaying seaweed cast up by the sea, shows plainly that the greatest caution must be observed in drawing any such conclusions.

Zoological Gardens, N.W. F. E. BEDDARD

THE ACTION OF AMMONIA UPON SOME LEPIDOPTEROUS PIGMENTS

TWO or three years back, some entomological friends induced me to kill all my insects with ammonia, instead of employing potassium cyanide, and I have never regretted the change I then made. Nearly the first species so treated was *Melanargia galathea*, and on opening the pill-boxes I was much surprised to find every one of them of a beautiful primrose-yellow colour. In a few moments the primrose-yellow had vanished and the insects were of their normal white again. Evidently this phenomenon was due to the volatile ammonia, so I held a specimen over the bottle, and instantly the primrose colour returned, only to disappear again with the departure of the pungent ammoniacal fumes. The reagent employed was a saturated aqueous solution of ammonia, and the black pigment of the wings remained unchanged throughout. Now here was something of great interest and well worth investigation, so I determined to follow it up, and since that time have never lost an opportunity for experiment or study. Many of my friends are now familiar with the results obtained, but as they appeared to be previously unknown to all those with whom I have communicated on the subject, I have thought it best to place them on record. They may be well known and authenticated, but to ascertain this a careful search through the vast mass of the chemical and microscopical literature both of this country and the Continent would be required, and for this my spare time is quite inadequate. I must therefore crave the indulgence of those who may be familiar with the facts herein recorded. Naturally, the first species selected for experiment was *Melanargia galathea*. As before, ammonia gave the primrose coloration. The next reagent employed was a solution of potassium hydrate, in which pieces of the wing were placed, and they immediately turned yellow. Other alkalis, such as solutions of sodium hydrate and barium hydrate, were tried, and gave similar results, the only difference being that with the fixed alkalis the primrose coloration was permanent, whereas with ammonia it was necessarily fleeting.

As alkali turned the pigment yellow, acids I thought might prevent this, or even produce another colour. Accordingly the wings were treated with a great many acids, the chief being sulphuric, nitric, sulphurous, hydrochloric, phosphoric, and acetic. With all these, when used in excess of the alkali, the pigment was restored to its natural white colour. I also found, that whenever the liquid employed was exactly neutral to both red and blue litmus, the pigment remained unchanged, whilst the slightest addition of alkali produced the primrose-yellow, and when acid predominated the normal colour prevailed. Thus, we see, this pigment is a good test for alkalinity.

To enumerate all the species experimented upon would occupy too much space, so I will only give the most important. As some Continental species are mentioned, I have followed Staudinger's arrangement. *Papilio machaon* and other Papilios were unchanged, and the same may be said of the genus *Thais*. *Parnassius apollo*, *P. delius*, and *P. mnemosyne* turned a pale yellow. With such semi-transparent species a deeper coloration could not be expected, from the small amount of pigment present.

None of the species of *Aporia*, *Pieris*, or *Anthocharis* showed any alteration with ammonia, but *Leucophasia sinapis* and its vars. *lathyri*, &c., exhibited a delicate primrose colour. Not a single species in *Colias*, *Rhodocera*, *Thecla*, or *Polyommatus* was changed; but the behaviour of the species of *Lycæna* was extremely curious and somewhat unexpected. *L. argiades*, *L. argiolus*, *minima* (= *alsus*), *semiargus* (= *acis*), *alcon*, *arion*, and *euphemus* remained unaltered. *L. bætica*, *argyrotoxus* (= *ægon*), *argus*, *optilete*, *orbitulus*, *eros*, *icarus* (= *alexis*), *eumedon*, *amanda*, *bellargus* (= *adonis*), *meleager*, *jolas*, and especially *astrarche* (= *agestis*), *corydon*, and *damon* were beautifully suffused with primrose on the under side and cilia, wherever the white pigment occurs. It is difficult to say why some of the species in this genus are unaffected, whilst others exhibit the most gorgeous colouring; but in the case of *L. argiolus*, at least, this may be accounted for. The pale bluish white of the under side is not the result of white pigment at all, but is due to reflected light from the almost pigmentless scales, in which a change could not be looked for. All the species which were examined in *Nemeobius*, *Charaxes*, *Apatura*, *Limenitis*, *Vanessa*, *Melitæa*, and *Argynnis* exhibited no change. In the Satyridæ, besides *Melanargia*, *Œnis aëllo* is clearly suffused with primrose beneath. In *Satyrus*, *S. circe* and *S. briseis* have the white bands changed, but *S. alcyone* and *S. semele* are not affected. *Erebia* and *Pararge* are alike unchanged. *Cœnonympha hero*, *C. arcania* (and vars.), *C. pamphilus*, and *typhon* (= *davus*), have the cilia and under side deeply suffused with yellow. Of the Hesperidæ, *Spilothyrus alceæ*, *Syrichthus alveolus*, *S. serratulæ*, and *malvæ* (= *alveolus*), all have the whites changed to primrose, but *Nisoniades*, *Hesperia*, and *Carterocephalus* are not affected.

With the *Heterocera* I have obtained but negative results, although the number of species operated upon are to be counted by hundreds. It would be unsafe to generalise with such scanty data to go upon, but a few remarks may be ventured. The white pigmentary deposits of *Pieris* and *Melanargia*, although to the eye the same, must have a very different chemical constitution, and at one time I thought the negative ammonia results would be a good character of the Pieridæ, in contradistinction to *Melanargia*, &c.; but facts would not support this speculation, for *Leucophasia* proved refractory, and the Satyridæ gave results by no means uniform. Many more experiments must be performed. Nature must be thoughtfully questioned again and again before we can possess a firm basis for speculation.

Hitherto changes of colour only have been dealt with, and few reagents employed, but by recent experiments on the solubility of the various pigments in different media, most interesting facts have been brought to light, which in the future I hope to communicate. What a wonderful and lovely sight is the under side of *Vanessa atalanta*! It has at least a dozen shades of colour, most exquisitely mingled. Some day these colours will be analysed and their constitution made known. The results herein recorded may then be of service.

GEORGE COVERDALE

24, Fleming Road, Lorrimore Square, S.E., August 16

SCOTTISH FISHERY RESEARCHES

APPENDIX F of the Report of the Scottish Fishery Board contains a series of valuable papers with accurate and well executed plates. Dr. Stirling gives a preliminary report on "The Chemistry and Histology of the Digestive Organs of Fishes." The first part gives the results of chemical investigations of the digestive processes in the herring, cod, haddock, and skate. The second part deals exclusively with the intestinal tract of the herring. The muscular coat of the œsophagus consists of striped muscular fibres arranged more or less regularly at the upper part, but disposed circularly in several layers at the lower. The mucous membrane of the œsophagus has longitudinal folds, and is lined with cylindrical epithelium interspersed with numerous goblet cells. The œsophageal glands are simple tubular glands, with, at first, a very short secreting portion. The glands in the "cardiac sac," or "crop," are, like those of the œsophagus, branched tubular glands lined in their upper part by tall columnar epithelium, and in their secretory parts by a single layer of cubical cells, like the "outer" cells of the fundus in mammals. The gland tubes become shorter towards the lower part of the cardiac sac, and they are absent in the pneumatic duct, which is lined by a single layer of columnar epithelium, and divided into two compartments by folds of the mucous membrane. Dr. Stirling has found that the organ which has been hitherto known as the "crop" in the herring, is something more than a mere receptacle, and corresponds in structure and function to the cardiac portion of the stomach of higher vertebrates. There is a striking resemblance between the cells lining the secretory portion of the gland tubes and the "outer cells" in the mammalian stomach, the point of difference being that the tubes are lined by a single continuous layer of these cells. There are apparently no internal layers of cells comparable to the inner cells of mammals, and, as might be perhaps expected, the glands are simpler than those of the mammals, and without that differentiation of tissue which is brought about by specialisation of function. One cell may subserve two functions, and, from an evolutionist's point of view, the secretion of an acid and the formation of a ferment have not as yet in the fishes been relegated to two distinct sets of cells. The pyloric sac or stomach is that short tubular organ with thick muscular walls, and resembling a gizzard, which opens out of the crop and is continued into the intestine. The surface of the mucous membrane consists of irregular depressions, which are deeper than those of the cardiac sac and may be regarded as crypts. The pyloric sac is always lined by a very thick coating of mucus, which not only lies on the surface, but dips down into the pyloric crypts. The surface of the pyloric sac and the glands or crypts are lined throughout with a single layer of tall, narrow, columnar epithelium, having the same character as that which lines the gland ducts and the surface of the cardiac sac. There is no muscularis mucosæ. The circular muscular coat is very thick, while the longitudinal is thin. Structurally the pyloric sac is comparable to the pyloric end of the mammalian stomach. Plates i. and ii. give series of figures illustrating various points in the anatomy of the intestinal part of the herring.

Prof. Macintosh gives a short note of preliminary observations made at the Marine Station, St. Andrew's, on the ova of various food fishes. Cod ova were specially examined, and experiments made as to their buoyancy and the effects of impure water, which proved very marked, and of changes of temperature. The small size of the yolk-sac, as well as the activity shown from the first by the newly-hatched fish show that they must soon take in nourishment from without. The ova of the common flounder were successfully hatched out. Other forms examined and experimented on were the long rough dab, turbot, *Cyclopterus lumpus*, herring, &c., and amongst invertebrates the ova of squids, *Natica*, whelk, nudibranchs, mussel, *Asterias rubens*, lobster, and shore-crab.

The vexed question as to whether the sprat is a separate species of the Clupeidæ or merely the young of the herring is satisfactorily settled in favour of the former opinion in the first part of the Report on the Sprat Fishing during the Winter of 1883-84, by J. Matthews Duncan, F.R.S.E., in which definitions of the differences in external and internal characters are distinctly proved. The sprat is more graceful in shape and slightly thicker in body than the young herring. The dorsal surface of the head is proportionally slightly longer in the herring, the operculum therefore extending further back. The suboperculum in the sprat is shorter and more triangular. The lower jaw is always longer and the diameter of the eye rather larger in the herring. In both sprat and herring the lower edge of the belly from the anal fin forwards is covered by a series of scales, having a central longitudinal "keel" and two lateral rays projecting forwards and upwards. These are more numerous but weaker in the herring than in the sprat, where the central keel is stronger and the termination forms a sharp point, so that the difference can easily be felt. In the sprat the pelvic fin is anterior to the first ray of the dorsal, whilst in the herring it is posterior to it. The pectoral fin is placed proportionately further back in the herring, and the centre of the dorsal slightly behind the centre of the body. The position of the dorsal fin varies more in the sprat, the position of the anal fin more in the herring. The number of rays in the pectoral, dorsal, and anal fins is not constant in either species, but appears invariable in the pelvic fin, that of the herring having two rays more. The arrangement of the teeth in both species is the same on the maxillæ, premaxillæ, and tongue, but those on the tongue are smaller in the sprat, and the vomerine teeth present in the herring are entirely wanting. The same superiority, as far as number is concerned, shown by the herring in the fin rays, scales, &c., is seen in comparison of other organs, the vertebræ, gill-rakers, and filaments, the branchial and pseudo-branchial filaments, and the branchiostegal rays, being all more numerous than in the sprat. The pyloric cæca are also more numerous. The slender duct by which the stomach (crop of Huxley, NATURE, vol. xxiii. p. 607) communicates posteriorly with the swim-bladder is slightly shorter and thicker in the sprat. In the herring the anterior end of the swim-bladder gives off two delicate branches, which run forward at first along each side of the parasphenoid, then diverge, and enter a small spindle-shaped capsule. From the anterior end of this capsule the duct passes out, and divides into two branches, one of which runs straight forward from the vesicle, whilst the other passes outwards at nearly a right angle. In the herring the ducts are very delicate tubes, measuring, in a herring 120 mm. long, 0·9 mm. in diameter, and are surrounded by a cartilaginous sheath, ·25 mm. in external diameter. The ducts meet posteriorly in the middle line, and open by a single aperture into the narrow anterior end of the swim-bladder. The spindle-shaped capsule is about 1 mm. long by ·6 mm. broad, and the spherical capsules are about 1·3 mm. in diameter, the anterior one slightly larger. The sprat, however, shows a remarkable departure from this arrangement. The ducts are about the same size as, and their form and direction are similar to, those in the young herring, though, at the point where they diverge from the parasphenoid (about 5 mm. from the swim-bladder) they lie higher, and are more difficult to follow. But the duct on each side ends in a *single* capsule only, exactly similar to that of the herring, and it neither forms a spindle-shaped dilatation, nor gives off a branch to a second vesicle. Thus, while in the herring there are three vesicles on each side of the head, all containing air, in the sprat there is only one. The foregoing differences are so numerous and so constant at all seasons that there can be no question as to the sprat being a distinct species from the herring, a further proof being that the former is found with developed milt and roe. Mr. Matthews shows in Plate iii. the difference between sprat and herring in the shape of the body and the keel scales, in the size of the ova, and in the formation of the air-vesicles of the ear.

In the valuable paper on the "Natural History of the Herring" Prof. Cossar Ewart, Convener of the Scientific Committee, treats of the varieties of the herring, the migration, the spawning-ground, the process of spawning, and the artificial fertilisation and hatching of ova. The varieties of the herring have long been discussed in all countries frequented by this fish, and differences believed to exist not only between herring of different countries, but of different districts and seasons. How far this may be true could not be determined even by careful examination and figuring of over 500 specimens, taken at different parts of the coast during winter and spring. Comparisons of outline show not so much that the herring of one district differ from those of another, but that there is a remarkable variation amongst herring caught at the same time. Heincke ("Varietäten d. Herings. Jahrb. d. Comm. in Keil, 1876-78") considers the position of the dorsal and pelvic fins of great importance, but, as specimens examined of the same length, caught at the same place, and as nearly as possible at the same stage of maturity, showed more difference than Heincke finds in his autumn and spring herring, some better character must be

considered requisite. It seems unlikely that the same herring spawn twice a year, but that the fish which spawn in the spring and autumn of one year do not spawn again respectively till the spring and autumn of the next year, in which case it is difficult to account for two distinct races of herring. It may be supposed that at first all herring were in the habit of spawning about the same period, but as time went on they were found spawning during every month of the year. Specimens of ova, for example, have been sent nearly every week from the Aberdeenshire coast, showing that herring have been spawning uninterruptedly in one district for at least ten months, from August 1883 to June 1884. The explanation of why at the present day there are two great spawning periods is not that spring and autumn are the two best periods for the depositing and hatching of the eggs, but that these are the two most favourable periods for the appearance of the fry, as then the surface-forms on which they feed are more abundant, as examination of the Ballantrae Bank showed. In the case of the herring the number of individuals does not depend so much on the number of eggs hatched as on the number of fry that survive. These when hatched are at first protected by their minute size and great transparency, and, given sufficient food, are likely to pass safely through the larval stage. If the larval food were more abundant in autumn and in spring, more fry would naturally survive at these periods, and this would ultimately result in the formation of great shoals of autumn and spring herrings. All that has been written on the migration of the herring leaves us still very much in the dark as to either the extent or the causes of it. Meantime, we may suppose that the movements of the herring are regulated during a greater part of the year by the supply of food, which naturally renders their movements very inconstant, and during the rest of the year by what may be termed their spawning instinct. This seems to imply several things, but it specially leads the herring to select ground suitable for the deposit of eggs, waters having a suitable depth, and water which will provide abundant food for the young fry. It has been long known, and was placed beyond doubt by the Fishery Board investigations of 1862-63, that herring were wont to spawn on hard ground. A very complete survey of the Ballantrae not only corroborated this fact, but showed that the herring even preferred to deposit their ova in the basin-shaped gravel-coated areas, where presumably the water is stiller than over the stone-covered ridges, and where it covered many square yards with a layer nearly half an inch in thickness. Eggs were also often found arranged in low masses over the surface of the long stems of laminaria. In several instances the dredge had apparently come upon part of the bank where the eggs lay "to a very great depth," but on examination it was found that the spawn, instead of forming thick masses, was arranged in irregular heaps ranging from a quarter to half an inch in thickness, and varying in size from scarcely an inch to nearly six inches square. By laying the portions side by side in a tank it was possible to obtain a very accurate notion of the arrangement of the undisturbed ova, which certainly often form a regular layer covering several yards of the bottom. On the east coast, judging from the specimens brought up by the long-line fishermen, the herring seem to select hard ground plentifully covered with sea firs, especially *Hydrallmannia* and *Antennularia*. Fishermen and others believe that there is some relation between the herring deserting any given spawning-ground—such as the once much-frequented bank off Dunbar and the equally famous Guillam Bank in the Moray Firth—and the loss of herring-nets during storms, or when over-fished. The reason is that nets loaded with putrefying fish, when left on the ground, cause the herring to seek more agreeable banks elsewhere. This pollution would be continued and extended by portions of the net continuing to fish during the whole season, so that not only might the eggs first deposited be destroyed, but fish which might have spawned on other portions of the bank be taken, and their eggs, though shed, rendered useless. In this way not only the greater part of a shoal, but, what is of even greater importance, nearly all the eggs deposited during the spawning period might be destroyed, and the survivors of the com paratively small brood hatched desert their birthplace as spawn ing-ground and cast in their lot gregariously with the first large shoal they met with. In the artificial fertilisation and hatching of herring ova the natural process of spawning was followed as far as possible, and many thousands of eggs treated in this way on March 8 hatched out on March 28, 29, and 30, the temperature varying from 41° to 44° F. When the eggs had been plentifully supplied with pure water, the extremely active embryos kept revolving or wriggling inside the capsule, till this ruptured and allowed the larval herring to escape head-foremost. But if the supply of pure water had been limited, the capsule gave way prematurely, the long, slender body escaped, but the head remained within, and the embryo usually perished in spite of all efforts to escape. The hatching was greatly expedited by the temperature of the water being slightly raised. As soon as the fry escape, they begin to try and ascend towards the surface, which they generally succeed in reaching on the fourth day, when they are found swimming freely about. This instinctive desire to rise to the surface as soon as they escape from the egg-capsule is evidently intended to bring them to the vicinity of the food, on which, after the fourth or fifth day, they depend for nourishment. Sketches are given (Plates iv. v.) of herring, illustrating the different positions of the fins. A map of the Ballantrae spawning-bank (Plate vi.), and drawings of a colony of *Hydrallmannia falcata* (Plate vii.) and *Antennularia antennina* (Plate viii.), with cluster of eggs attached. A series of figures (Plate ix.) show the eggs deposited artificially on glass and naturally on stones, gravel, and on a lost net dredged at Ballantrae.

A number of interesting specimens received by the Board are likewise described and figured:—(1) A new Blenny (*Lumpenu lampretæformis*, Plate x.), believed to be the first specimen recorded from the shores of the British Isles; it measured 10·7 inches in length, and was taken in forty fathoms of water, fifteen miles off St. Abb's Head. (2) A fine *Torpedo nobiliana* (Plate xi.) taken off Lybster in forty fathoms of water. (3) A Comber (*Serannus cabrilla*, Plate xii.) taken off Shetland, the first recorded in the North Seas. (4) A Turbot (*Rhombus maximus*, Plate xiii.), dark on both sides, with an eye on each side of the head and rounded frontal process, taken off Anstruther. (5) A splendid Opah (*Lampris luna*), four feet in length, taken in seventy-five fathoms of water off Fluga, Shetland, and now being examined by Prof. Turner, F.R.S. Another item is a list piled by Miss Maclagan of edible British fishes and mollusks, with their Latin, French, Italian, and German synonyms.

THE BRITISH ASSOCIATION

SECTION D—BIOLOGY

Department of Zoology and Botany

Remarks on the Characteristic Features of North American Vegetation, by Prof. Asa Gray.—The first impression produced on a visitor from Europe to the Atlantic coast would be the similarity of the flora to that of England, many of the plants being almost or quite the same. The larger number of these are obviously introduced. The mullein, the toad-flax, the ribworts, the milfoil, the clovers, thrive by every roadside as in England, and perhaps with even greater luxuriance, the competition being less. This strongly suggests the idea that the distribution of plants is not always due so much to adaptation as to opportunity. As one proceeds westward and southward, the difference becomes more marked, the European type gradually disappearing. But as European settlements extend, the settlers carry their plants with them, and the plants are well up to the time, and travel by rail. On the other hand, some plants, but a much smaller number, are carried from America to Europe, and naturalised there. Such are *Impatiens fulva* and *Erigeron canadensis*. Turning from similarities to differences, one of the first points that strikes a European visitor is the great wealth of trees and shrubs. This Prof. Gray illustrated by giving the number of European and North American species in the most important arborescent orders. The reason of this is probably to be found in the different conditions of the two continents during the period of glaciation. The flora of Europe is exceptionally poor in trees, and, on the return of a warmer climate, the return northwards of those that survived in the south was barred by the Mediterranean. The fossil remains of trees belonging to many tropical orders are found in our Miocene and Pliocene strata. In America, on the contrary, there was nothing to prevent their gradual return from the south, and accordingly we find solitary examples, or in some cases a larger number of representatives, of many tropical orders among the trees of the Northern States. Such are *Menispermum* (Menispermaceæ), *Liriodendron* (Magnoliaceæ), *Diospyros* (Ebenaceæ), *Tecoma* (Bignoniaceæ), and many others. This difference is also promoted by the greater heat of the American summer as compared with that of Europe. On the high lands of North America are also many Arctic plants, which

remained after the Glacial period had passed away; but this flora is insignificant compared with that of Europe. A few species are found on the cool shores of Lake Superior, the shores of Labrador, and certain summits of the Appalachian Mountains. One of the most interesting features of North American botany is an outlying region of a true tropical flora which extends northwards up the Atlantic coast as far as the "pine-barrens" of New Jersey. Proceeding westwards, whether in the States or in Canada, a gradual striking change is observed: not only do the European importations disappear, but European genera give place to those specially characteristic of the western continent. Here above all is to be observed the extraordinary wealth of Compositæ, which make up about one-eighth of the total phanerogamous flora of North America; great numbers of species of *Aster*, *Solidago*, *Eupatorium*, *Silphium*, and other genera. Between the wooded region of the Atlantic and the wooded region of the Pacific coast, there is an immense tract of woodless prairie land, the home of the "buffalo" and of many grasses; and in the spring the number of bright coloured herbaceous plants is also very large. These plains are destitute of water, and probably never grew trees, and are capable of growing nothing but herbaceous plants, which completely disappear in the hot dry summer. Then comes the great chain of the Rocky Mountains, which are well wooded on their sides, and have on their summits a flora of about 200 Arctic species. When the traveller reaches the Sierra Nevada, he enters perhaps the noblest coniferous forest in the world. But while the Pacific coast is extraordinarily rich in Coniferæ, it has a smaller number of trees belonging to other orders than the Atlantic coast; the entire absence of oaks, ashes, and maples, is especially remarkable.

Observations on the Trapping of Young Fish by "Utricularia vulgaris," by Prof. Moseley.—Small perch just out of the ovum were found in the bladders of *Utricularia vulgaris*, some of them caught by the head, some by the tail; but very close observation failed to detect the actual act of capture. No process of digestion has been discovered, and the object of the capture requires further investigation.

On the Jessop Collection, to Illustrate the Forestry of the United States in the New York Natural History Museum, by Albert S. Bickmore.—The great importance of the forest industries and lumber trade of the United States led Gen. Walker, the Superintendent of the Tenth Census, to provide for a corps of competent experts, under the direction of Prof. Charles S. Sargent, who have made new explorations of our forest lands, and gathered original data regarding their present extent. The results of these elaborate researches have been partially published from time to time in the form of bulletins, and the completed work will soon appear in two large quarto volumes of the census series. To place this great fund of valuable information before the artisan and labouring classes in an accessible form, a great collection of our forestry and its products was needed, and this Mr. Morris K. Jessop offered to provide at his own expense. After the field work planned by the census had been finished, Prof. Sargent directed his assistants to return to the forests, and to carefully select the individually largest and soundest tree of each species. Prof. Sargent is preparing a manual which will be a guide to the collection, and which contains all the most important information in the large census volume that will be useful to the visitors and to the artisan classes. The museum is most fortunate in its location in Central Park, where more native and domesticated species are flourishing than can be seen together at any other place on the continent. This is the first effort yet made in this country to gather the native woods together into one collection on a scale commensurate with the extent of the new continent and the importance of its forests.

On the Origin of Fresh-water Faunas, by W. J. Sollas.—The author commented on the lack of interest which had been previously taken in the subject, and then referred to the experiments made by Bourdon in changing salt water into fresh. The old idea that salt water had been the mother of life was now generally acknowledged. In the River Jumna, one thousand miles from its mouth, were found marine forms of mollusks. We had to look further than change of temperature and the composition of the water for the manner in which marine specimens obtained their distribution. The currents of rivers always flowed seaward, and if free-swimming larvæ got a short distance up a river they were certain to be washed down again. The case was different with swift-swimming fish, the Salmonidæ, for instance, which were able to swim up stream and lay their eggs in lagoons. According to a table which he had prepared, nearly all the groups of fishes were both fresh-water and marine. He referred to the evidence afforded by geology to show that fresh-water forms were but modifications of those found in salt water. He believed the sea-water fauna had become fresh-water fauna in the times when tracts of salt water had become fresh-water lakes. He dwelt on the subject of secluded development, and concluded that the higher the organism the less possible was it to diverge from the parent stem. The tree of life at the present time rather put out new leaves than fresh branches.

Prof. Murat of Harvard briefly criticised the paper. The subject was one, he said, rather for suggestion than dogma.

On the Concordance of the Mollusca inhabiting both sides of the North Atlantic, by Dr. Gwyn Jeffreys.—It was recommended that this paper should be printed entire in the *Proceedings*.

On the Identification of Animals and Plants of India which are mentioned by early Greek Authors, by Prof. Valentine Ball, F.R.S.—He said that upon examination it had been found that many of the animals mentioned by Herodotus, Strabo, and other Greek historians, which had usually been regarded as myths by commentators, were easily identified as animals which were found to-day in the forests of India. For instance, the marticora mentioned by old classical writers, and usually regarded as a combination of tiger and scorpion, was really a tiger. It was said by the Greek writers that the marticora had poisonous whiskers and a sting at the end of the tail. In India to-day the inhabitants still regarded the whiskers of the tiger as poisonous, and when one was killed they always took care to burn the whiskers. With regard to plants, Herodotus mentioned the "Indian reed" or *Calamus indicus*, which was generally regarded by scholars as the bamboo. This was, however, impossible, as the bamboo did not grow large enough to furnish material for canoes, as Herodotus expressly stated that the *Calamus indicus* did. The speaker thought it was the Palmyra palm which grew in the valley of the Indus, and which was known in the Sanskrit language as the "Father of Reeds." There were many others of these animals and plants which could be identified, and when the writer's investigations were published he hoped it would be found that he had exonerated the old travellers from the imputations which had been cast on their veracity.

On the Rudimentary Hind Limb of the Humpbacked Whale, Megaptera longimana, by Prof. J. Struthers.—He said the humpbacked whale was extremely rare on the British coast. One had been seen often spouting for some weeks in December in the Firth of Tay; it was mortally wounded, and finally towed ashore dead near Aberdeen. It was a male, forty feet in length. After it had been exhibited for a couple of weeks at Dundee he had partially dissected it. Having been preserved, it was further exhibited, and he had only completed his dissection immediately previous to coming out. The presence of a rudimentary thigh-bone had been discovered in this species many years ago by the late Prof. Reinhardt of Copenhagen. The thigh-bone was composed entirely of a cartilage of conical shape, in length five and a half inches on the right side, four inches on the left; it was incased in fibrous tissue, and rested loosely on the pelvic bone without articular surface. Looking at the anatomical facts and comparing them with those of the other species he had referred to, the conclusion which must be arrived at was that the thigh-bone in the humpbacked whale was a rudimentary structure, a vestige of a more complete limb possessed by ancestors, from which it was descended. The skeleton of this whale would be placed in the Dundee Museum, he hoped, before the Association met in Aberdeen next year.

On the Value of Nerve-supply in the Determination of Muscular Anomalies, by Prof. D. J. Cunningham.—He spoke of the muscula sternalis as a new muscle in man, which had no counterpart among animals. It was, according to his experience, found more frequently among females than males, while Prof. Sheppard, of McGill College, had, he learned, had three cases, all among males.

Prof. Moseley said that this subject of the anomalies of the muscles had a very important bearing in solving many of the riddles of the evolutionary theory.

Prof. Struthers said that while it was not at all impossible that new muscles were starting up within us, it was also possible that the muscles might have existed before, and not been discovered, as our predecessors did not examine things as closely as did the modern investigators in muscular anomalies.

Dr. G. E. Dobson regarded this muscle as a rudimentary vestige of a muscle found in all the lower animals, by the use of which they are enabled to draw in their head and forelegs when they erect their spine.

On the Mutual Relation of the Recent Groups of Echinoderms, by Prof. A. M. Marshall.—Of these there were four groups, the common starfish, brittle starfish, sea-urchins, and holothurians. He said the nerve-system was originally derived from the skin. In some animals the nerve system sank below, in others it remained near the skin, these latter being in a more primitive condition than those in which the nerve-system had sunk down.

Prof. Moseley characterised the paper as very valuable, having fully borne out all the discoveries of Prof. Carpenter, whose advancing age had prevented his being present.

A paper *On the Fœtal Membranes of the Marsupials*, by Mr. A. H. Caldwell, who was sent to Australia by the British Association to investigate certain interesting biological questions, was read, in his absence, by Mr. Sedgwick. It gave an account of the development of the marsupial embryo, which has been hitherto a riddle in biology. A letter from Mr. Caldwell as to the progress of his investigations in Australia was also read.

On Some Peculiarities in the Geographical Distribution and Habits of Certain Mammals Inhabiting Continental and Oceanic Islands, by G. E. Dobson, M.A., F.R.S.—The geographical distribution of mammals inhabiting continental and oceanic islands has been lately so ably treated of by Mr. Wallace, in his work "Island Life," that I do not purpose entering upon the subject from a general point of view, but will limit my remarks to some peculiarities of distribution which have attracted my attention while engaged in the special study of certain mammalian orders: I refer particularly to the Chiroptera and Insectivora. It is an interesting fact, not hitherto noticed, that many of the most characteristic species of the Chiropterous fauna of Australia have their nearest allies, not in the Oriental, but in the Ethiopian Region, thus contrasting remarkably with the avifauna. The remarkable genus *Chalinolobus* is represented only in Africa south of the equator and in Australia, a single species extending into New Zealand. Again, the species of the sub-genus *Mormopterus*, which belongs to a genus (*Nyctinomus*) of world-wide distribution, is limited to the same zoological regions, being found only in Africa south of the equator, Madagascar, the Mascarene Islands, Australia, and Norfolk Island. The presence of a species of this genus in Norfolk Island and its absence from New Zealand is very remarkable, for, as I pointed out for the first time about ten years ago, one of the two New Zealand bats known, namely *Chalinolobus tuberculatus*, is also common in Australia. The species of the extraordinarily specialised genus *Megaderma* have their headquarters in the Oriental and Ethiopian Regions; yet the largest species not only of the genus, but also of all known insectivorous bats, namely *M. gigas*, lately described by the writer from Central Queensland, has its nearest ally, not in any of the Oriental species, but in *M. cor* from Eastern Africa. Another very remarkable leaf-nosed bat, the type of my genus *Triænops*, found in Madagascar, Eastern Africa, and Persia, but unknown in the well-searched Oriental Region, has its nearest and only ally in *Rhinonycteris aurantia* of Australia, the type of another very peculiar genus. Finally, Australia agrees much more closely with Madagascar and the Mascarene Islands than with the Oriental Region in the species of the large genus *Pteropus*, for, while species of the section of which *Pt. vulgaris* of Madagascar is characteristic are well represented in the former regions, they are absent from the latter. Furthermore it is noticeable that, while 80 per cent. of the species of the genus inhabit the Australian Region and Madagascar with its islands, a single species only has found its way to the great continent of Hindostan and to Ceylon.

On the Geographical Distribution of the Laridæ (Gulls and Terns) with Special Reference to Canadian Species, by Howard Saunders.

Result of the Investigations of Insular Floras, by W. B. Hemsley.

Some Observations on the Direct Descendants of Bos primigenius in Great Britain, by G. P. Hughes.

On Natural Co-ordination as Evinced in Organic Evolution, by Dr. W. Fraser.

Department of Anatomy and Physiology

On the Presence of Eyes and Other Sense-Organs in the Shells of Chitonidæ, by H. N. Moseley, M.A., F.R.S., Linacre Professor of Human and Comparative Anatomy in the University of Oxford.—The Chitonidæ have hitherto been regarded as characterised by an entire absence of organs of vision, the presence of eyes in the shells of numerous genera having been entirely overlooked by naturalists. The author first discovered eyes in a specimen of *Schizochiton incisus*, dredged by Capt. Chimmo, R.N., in the Sulu Sea, in which species they are larger and more conspicuous than elsewhere, and on examining carefully the shells of certain other forms, found eyes present there also. The eyes are entirely confined to the shells, and to the exposed parts of these, the "tegmenta" not occurring at all on the "articulamenta." They never occur on the girdle or zone, or any other part of the mantle. They appear as bright, highly-refracting, convex beads on the shell-surfaces, encircled by zones of dark pigment formed by the choroid layers. The eyes are usually circular in outline, and very minute, measuring in *Schizochiton incisus* about 1/175th of an inch in diameter, in *Acanthopleura spiniger* 1/350th of an inch, and in *Corephicum aculeatum*, in which they are oval in outline, 1/600th of an inch by about 1/400th. In the case of all the intermediate shells the eyes are confined to the areæ laterales, or to the lines of demarcation between the areæ laterales and the area centralis, which latter is usually entirely devoid of them. In some genera of Chitonidæ, such as Acanthopleura and Corephicum, the eyes appear to be often destroyed and obliterated in the older regions of the shells by decay and delamination of the tegmental surface, or its destruction by boring Algæ or animals. They are, however, constantly re-formed by the mantle in the process of growth of the shell at the growing margin of the tegmentum, and may be observed in this situation in all stages of construction. In other genera, such as Tonicia, the eyes lie in shallow pits of the shell-surfaces, and thus escape destruction by wear, nearly the entire number which have been formed being thus found present in fully-grown shells. The tubercles and prominences by which the tegments are covered in some forms serve, perhaps, as protections to the eyes from attrition. The entire substance of the tegmentum in the Chitonidæ is traversed by a series of branching canals, which are occupied in the living animal by corresponding ramifications of soft tissue and nerves. The strands of soft tissue are continuous with the tissues of the mantle along the line of junction of the margin of the tegmentum with the upper surface of the articulamentum by means of a series of tubular perforations in the shell-substance. Further, in the intermediate shells of most genera there are a pair of lateral slits (incisuræ laterales), one on either side in each shell in the lateral laminæ of insertion; these slits lead each to a narrow tract in the deep substance of the shell, which follows the line of separation between the area centralis and area lateralis. This tract is permeated by longitudinal canals, into which open a series of five apertures on the under surface of the shell. By these apertures numerous nerves enter the tract from the bed of the shell, and, traversing the longitudinal canals, give off a series of lateral branches on either side from it to the network within the tegmentum. In the cases of the anterior and posterior shells, there are usually a considerable number of slits present in the laminæ of insertion, each connected with a similar nerve-supply to the tegmentum. The network terminates at the surface of the tegmentum all over in a series of elongate cylindrical organs of touch, the plug-like ends of which are somewhat dice-box shaped, and can be protruded beyond the level of the tegmental surface from a series of pores, "macropores," by which this surface is covered. These larger organs of touch give off from their sides five branches of soft tissue, which pass vertically to the surface of the tegmentum, and terminate there in minute plug-like organs like the larger ones, but much smaller, and which are protrusible from a series of smaller pores (micropores) in the shell-substance. These smaller and larger touch-organs, and their corresponding pores, are disposed on the surface of the tegmentum with more or less exact regularity in different genera of Chitonidæ; in many cases in very definite lines and patterns. The eyes are connected with the same network of soft tissue as the touch-organs, and are apparently to be regarded as having arisen in development as special modifications of them. The soft structures of each eye lie in a more or less pear-shaped chamber excavated in the substance of the tegmentum. The stalk of the pear, which forms the canal for the passage of the optic nerve, is directed always towards the free margin of the tegmentum, and here its wall is pierced by a circular aperture, which is covered by the cornea. The cornea is calcareous, resisting the action of strong boiling caustic alkalis, but collapsing at once when treated with acids.

In section it is seen to be composed of a series of concentric lamellæ. Its substance is continuous with the general calcareous substance of the tegmentum at its margins. The pear-shaped cavity of the eye, formed by the shell-substance, is lined by a dark brown pigmented choroid membrane of a stiff and apparently somewhat chitinous texture. This membrane exactly follows the shape of the cavity, but, by projecting inwards beyond the margin of the cornea all round, forms an iris of a less diameter than the latter. A perfectly hyaline, strongly bi-convex lens is placed behind the iris aperture. It is composed of soft tissue, and dissolves in strong acetic acid. The optic nerve at some distance from the retina is a compact strand, but before reaching the latter has its numerous fine fibres separated and loose. The retina is composed of a single layer of rather short but extremely distinct nucleated rods of roughly hexagonal section, with their free ends presented to the light. Immediately behind them is a dense mass of nerve-fibres with numerous nuclei and nerve-cells interspersed. The retina is on the type of that of Helix, and not, as might have been supposed, on that of the dorsal eyes of Oncidium. A large part of the peripheral fibres of the optic nerve do not pass to the retina, but pass outside the eye-chamber by a series of apertures in the choroid round the iris margin, and end at the shell-surface in a zone of touch-organs encircling the eye. The touch-organs are identical in structure with the smaller touch-organs already described as appended to offsets of the larger touch-organs all over the shell. In giving off nerves to a series of such small organs, the eye thus corresponds exactly in structure to these larger touch-organs, and its homogeny with them is thereby clearly indicated. The arrangement of the eyes varies much in the different genera. In *Schizochiton incisus* the eyes are restricted to single rows traversing the lines separating the lateral area from the area centralis, and corresponding in portions with the incisuræ laterales and courses of the principal nerves. There are six rows of eyes, with six marginal slits on the anterior shell, and six on the posterior, and a single pair on each of the intermediate shells, twenty-four rows in all, with an average of about fifteen eyes in each, or, in all, 360 eyes. In *Acanthopleura spiniger* the eyes are irregularly scattered around the bases of the tubercles with which the surface of the tegmentum is covered, and are confined in the specimens examined to the region of the margins of the shells adjoining the mantle. The surface of the older regions of the tegmentum seems in this species especially liable to flake off, carrying the eyes with it, and it will probably be found, when series of examples of various ages are examined, that the eyes are originally more widely extended over the shell surfaces. In *Corephium aculeatum* the eyes are very small, with corneas oval in outline, the long axis of the oval being directed vertically to the shell margin. They are never placed on the tubercles with rows of which the shell-surface is covered, but between the bases of these. The two kinds of pores lodging the organs of touch are arranged in vertical parallel lines with great regularity, the large pores occurring at intervals in the lines of smaller pores. The eyes are present in enormous numbers, the anterior shell alone bearing more than 3000, and the entire eight shells more than 11,500. In *Tonicia marmorata* the eyes are arranged in single straight radiating rows on the anterior and posterior shells. On each lateral area of the intermediate shells there are from two to four similar rows of eyes. In Ornithochiton the eyes are disposed somewhat similarly. In the genus Chiton, eyes appear to be entirely absent, though the touch-organs of two sizes and corresponding pores are present. In Molpalia, Mangina, Lorica, and Ischnochiton, I have as yet detected no eyes. In Chitonellus there are no eyes, and the supply of touch-organs is scanty and confined to the margins of the tegmenta. The arrangement and structure of the eyes and organs of touch will probably be of great value in the classification of the Chitonidæ, which has hitherto proved so difficult a problem. No traces of any structures resembling the eyes and touch-organs of the Chitonidæ can be detected in the shells of Patella or allied genera. The tegmentary part of the shells of this group appears to be something *sui generis*, entirely unrepresented in other Mollusca. Its principal function seems to be to act as a secure protection to a most extensive and complicated sensory apparatus, which in the Chitonidæ takes the place of the ordinary organs of vision and touch present in other Odontophora, and fully accounts physiologically for the absence of these latter in them. Dr. W. B. Carpenter observed the perforate structure of the tegmentum in Chiton, though he did not examine the nature of the contained soft network. The late Dr. Gray, in his well-known paper on the structure of Chitons, recognised the fact that the tegmentum in the Chitonidæ is something *peculiar* to the shells of this family.

On a Method of Studying the Behaviour of the Germs of Septic Organisms under Changes of Temperature, by Rev. Dr. Dallinger.—Description of a new apparatus invented for this purpose.

A Vegetable Organism which Separates Sulphur, by A. W. Bennett.—Description of *Beggiatoa alba*, an organism found in the effluent water from sewage-works, known as the "sewage-fungus," which has the property of separating sulphur out of the organic matter in the water, or in the salt used in precipitating the sewage, in the form of minute sharply refringent globules.

On the Coagulation of Blood, by Prof. H. N. Martin and W. H. Howell.—The blood of the Slider Terrapin, a turtle easily obtainable in Baltimore, had been used for a number of experiments, the object of which was to determine whether the views entertained by Hammarsten or by Schmidt were most reliable. The general conclusions went to show that the views of Hammarsten were more in accordance with the results of these observers.

Prof. Schäfer asked if the authors had made any experiments with reference to the addition of lecithin and white corpuscles respectively to the blood plasma.

Prof. Martin replied that no experiments had been made with lecithin, but that he had found that the plasma did not clot when entirely free from white corpuscles or a watery extract of them.

On the Blood of Limulus polyphemus, by Francis Gotch and J. P. Laws.—The paper was chiefly interesting, as Prof. Schäfer remarked, on account of its indicating the combination of copper with a proteid replacing the usual iron.

On Vaso-motor Nerves, by Prof. H. P. Bowditch.—He gave an account of some experiments he had been making to determine the need of vaso-motor nerves. He had employed an entirely new method, namely, the use of the plethysmograph.

Demonstration of the Co-ordinating Centres of Kronecker, by Prof. T. W. Mills.—This subject had been previously practically demonstrated to most of the physiologists present. The view, rief, held by Prof. Kronecker is that there the ventricle of the dog's heart a centre which, when injured, is paralysed, and whose function of co-ordinating the muscular movements to form a beat is thus lost, the heart going into what is known as fibrillar contraction, which is wholly insufficient to propel the blood through the body.

Dr. Martin had seen this phenomenon when working on the coronary artery, and thought it due rather to injury of the nerves.

Prof. Schäfer held a somewhat similar view.

Dr. Bowditch asked if, as the injuries referred to were mostly superficial, they did not differ very much from the case in point, which was a deep injury.

Prof. McKendrick thought that if it was merely an injury of a nerve that caused the phenomenon, the heart might be brought back to its natural action; while the fact was a dog's heart, he understood, had never been recovered.

Dr. Mills also stated that Prof. Kronecker would, in consequence of injury of this centre, explain deaths from slight pricks of the heart, sudden death in heart disease in certain cases, and death from chloroform.

Prof. Schäfer thought that from the evidences it was clear electric excitation should not be used to recover hearts suffering from chloroform administration, inasmuch as the phenomenon could itself be caused by the application of an electric current.

Dr. Osler thought the strength of current usually used by physicians in such cases was not so strong as those Prof. Schäfer had in view.

On the Cardiac Nerves of the Turtle, by Profs. Kronecker and Mills.—This communication went to show that in the sea turtle there were nerves whose function was perfectly analogous to that of the vagi and accelerantes in mammals. The course of these nerves varied a good deal in different species and in different individuals. It had also been discovered that the pulsating great veins of the land turtle were under the influence of the vagus.

Prof. Martin had found in the Slider Terrapin a ganglion, apparently answering to the thoracic ganglion of the dog, from which the accelerator nerve passed to the heart.

On the Functions of the Marginal Convolution, by V. Horsley and Prof. Schäfer.—The object of their experiments was to ascertain the effect of stimulation of localised areas of the marginal

convolution in the monkey, and their results filled up a gap in the well-known work of Ferrier in that they were able to show that removal of certain areas, the excitation of which had previously caused movements of muscles of the trunk, &c., on both sides led to paralysis of muscles of the trunk of such a degree that the animal was unable to stand. By removal of the frontal lobes no paralysis of voluntary movements were obtained. These results were in opposition to those of Munk, of Berlin.

Ova of Monotremes.—The President stated that he had a most important announcement to make. He had just received a cablegram from Sydney, from Prof. Liversidge, announcing that Mr. Caldwell, the Balfour Student, who was sent out to Australia to investigate the mysteries in connection with the mammals of that country, had discovered that the Monotremes were oviparous. He did not consider that a more important telegram in a scientific sense had ever passed through the submarine cables before. The Monotremes formed two families characterised by the duck-billed Platypus and an animal which was known to the Australians as the ant-eater. These were the lowest forms of mammals, and it had never been known how they produced their young. The extraordinary discovery was now made that these mammals laid eggs, and that the development of these eggs bore a close resemblance to the development of the eggs of the Reptilia. This discovery proved that these animals were more closely connected with the Sauropsida than with the Amphibia.

On Sensory Nerve-Sacs in the Skin of Amiurus, a Siluroid Fish; and *On the Function of the Air-Bladder in Amiurus, and its Relationship to the Auditory Organ*, by Prof. R. Ramsay Wright.—He referred to the numerous species in North American fresh waters, and their remarkable uniformity, almost all belonging to one genus, Amiurus, while tropical fresh waters teem with many different genera differing extremely fr m each other in form. All the species, however, live in muddy waters, and, to make up for the want of the powerful eyesight which characterises the salmon, are provided with an exceedingly sensitive skin and with special tactile appendages on the head. The lecturer described the already known forms of sensory organs in the skin, and then pointed out that certain structures recalling the nerve-sacs of ganoid fishes, like the sturgeon and gar-pike, are scattered all over the body from head to tail, and both on the upper and lower surfaces. This diffusion of these organs is of interest as indicating probably an ancient type of their arrangement. The second point touched upon was the function of the air-bladder and its relationship to the auditory apparatus. Prof. Wright believes the fish becomes sensible of alterations in the pressure of the surrounding water in the auditory apparatus, and suggested that the air-bladder is also an important channel through which sounds are communicated to the terminal organs of the auditory nerve.

In the discussion which followed Prof. Alfred Haddon of Dublin confirmed the latter point, and suggested that this particularly delicate apparatus for receiving sounds was present on account of the fact that tropical Siluroids, at any rate, are capable of producing sounds by means of a stridulating apparatus, some forms of which he had himself described.

SECTION H—ANTHROPOLOGY

MR. HORATIO HALE read an interesting paper *On the Origin of Wampum.* He said that amongst the Indians it represented mammon, or money, and was equally valued. It had once been actually accepted in Massachusetts and New York as legal currency, owing to lack of silver, and was largely used in the Indian trade. Wampum consisted of a kind of bead or shell, but must not be confounded with the cowries of the East. Indians on the sea-coast drove a large trade in this article, and Long Island was a mine of wealth. The word wampum was of Algonquin origin, and meant white. The speaker explained the various uses to which this material was put. It was generally used in strings and belts, and at the great Iroquois ceremonies it was considered indispensable. Black wampum was more valuable than white. Of the many thousands of belts that had been known to exist during the last three centuries, scarcely fifty remained, and Mr. Hale regretted the dull indifference that had been displayed by the Americans with regard to this interesting and valuable material, valuable as forming a chronicle of the tribes who manufactured the belts. Mr. Hale exhibited an historical belt of wampum, composed of white beads, with four black squares, which, he said, represented four towns. This belt, he said, was one hundred and sixty years old. Another and still more remarkable belt was also shown by the speaker, who explained the emblems upon it, which, he said, were intended to represent the signs of the Christian religion. There were three crosses representing the Trinity, a lamb, executed in a primitive manner, and a dove. These objects, Mr. Hale said, had been evidently suggested to the Indian artist, who had done his best to represent them, but he said that his artistic powers should not be judged by this specimen. The speaker also displayed some strings of beads, and said that these were used in the Indian chants, the beads recalling certain verses to the singers. Mr. Hale showed to the Section a photograph of some Indian chiefs of the six nations who had met at Brantford and explained to him the meaning of their wampum belts. Shell beads, he said, were used in large quantities by the mound-builders, and he argued that it was probable that the art of manufacturing this medium had descended to the modern tribes from their more advanced ancestors. Some beads, which had been found in an enormous burial-place in Orillia county by Mr. Hirschfelder, were shown by Mr. Hale, who said that these were undoubtedly used by the Hurons. Crossing the Rocky Mountains, he said that wampum would be found in actual use, the material itself and the labour devoted to its ornamentation making it extremely valuable. Being susceptible of a high polish, it forms very handsome ornaments, and is better adapted for this purpose than for currency, for which it is cumbersome. Speaking of the amount of shell money possessed by the primitive Indians, Mr. Hale said that the average man owned about one hundred dollars' worth, that being, he said, about the value of two women, two grizzly bear skins, twenty-five cinnamon bear skins, or three ponies. Mr. Hale remarked on the districts in which wampum was found, and quoted some sentences from a work of his own with regard to the discovery of wampum in the Kingsmill Islands of Micronesia in the Pacific Ocean. There, he said, he saw strings of alternate wooden and shell beads. He exhibited to the Section specimens of beads from the Kingsmill Islands and from California, some of these having lost their lu tre from the long time which they had been buried in a grave. Mr. Hale made some interesting remarks upon the history of Chinese money or "cash," tracing its origin to the tortoise-shell disks used in earlier times. Mock money, he said, was sometimes burnt at sacrifices, as the Californian Indians burnt their shell money at funerals. He traced the passage of this currency between Asia and America, showing how it could have been brought from one district to another. It was used, he said, by Indians in Eastern North America, those in California, the inhabitants of Micronesia, and the Chinese. He thought that the monetary system was indigenous to China, and that by early intercourse it had been conveyed to this continent. He noticed the fact that Chinese junks and Micronesian prows may have been wrecked on the western shores of America, and that their crews may have introduced the system of shell money amongst the Indians.

Major J. W. Powell read a paper on *The Marriage Laws of the North American Tribes.* In the course of his observations, the speaker remarked upon the custom of burying articles with the dead. There were two classes of property amongst the Indians, communal, or that belonging to the tribe, and personal, or that belonging to the individual. In order to prevent controversy the latter was buried with its owner. With regard to the marriage laws, Major Powell said there were many strange customs. For instance, in some tribes, marriages were arranged by officers of the tribe, and the choice of wife or husband was limited to certain groups of persons. Marriage was therefore not by personal choice, but by legal appointment. But marriage could be performed by elopement, or running away, when, if the couple could remain in safety from detection and punishment until after the day of jubilee, or the day when all offences are considered forgiven, then that marriage would be considered legal. Wives could also be obtained by trial of battle, a contest of some kind, when the woman became the helpmate of the victor. There was also marriage by capture. The methods of obtaining a wife were so common that the custom of marriage by legal appointment was much neglected. But though this was the legal and proper method, the others had become legalised by long custom, and now the capture, contest, or elopement were merely simulated.

Mr. C. A. Hirschfelder of Toronto, as representative of the Numismatic and Antiquarian Society of Montreal, read a paper *On Prehistoric Remains in Canada.* The ancient remains of

Canada have, as yet, been by no means satisfactorily examined, and consequently but superficially described; and although we have no stone ruins, still that does not detract from the interest of the prehistoric works, found scattered over various sections of this country, which are well worthy of a thorough scientific examination. The forts, which were built principally of earth, although stone was not unfrequently used to some extent in their construction, are particularly interesting from two points of view—viz. the almost perfect symmetrical shape, and the advantageous positions which were invariably chosen. As to the first-named feature, they bear a striking resemblance to the ancient earthworks of the Western States, by which some writers have endeavoured to prove that the authors of those works must have been advanced in certain sciences. As to the situation of these forts, their ancient builders seem to have carefully studied localities, and to have fully appreciated the advantages to be gained thereby, as the situations chosen were invariably such as either to command a view for a long distance over the country, or, if near the water, to be so constructed that a fleet of canoes could be seen a long distance away, so that sudden attacks by water would be impracticable. The forts were generally made either circular or oval, although one or two surveyed were crescent or semi-circular, the form probably depending upon the lay of the land; and it is very singular that there has not been, to my knowledge, a single fort discovered in Canada which even approaches a square. Entrenchments seem to have been a not uncommon mode of defence, and have every appearance of being anterior to the wall or embankment forts; the largest one surveyed was half a mile in circumference, of a circular form, and, judging by counting the concentric rings of trees growing right in the ditch, which must have grown after the fort was constructed, also by decayed vegetable-matter and other evidences, was computed to be from 800 to 1000 years old. Ancient burial-places may be classed under three heads—mounds, ossuaries, and single graves. Mounds are not of frequent occurrence in Canada, and all which have so far been examined have contained human bones, proving that they were used as burial repositories. These tumuli (if they may be so termed) are not by any means large; they generally measure about 100 feet in circumference, and are only about 5 feet high. The dead seem to have been buried without any regular system, each mound containing from six to twelve bodies. The ossuaries are probably the most interesting remains we have. They consist of round symmetrical holes dug to the required depth, and into which the bodies were promiscuously deposited; some of the larger ones contain the remains of several thousand bodies. The single graves are the most ordinary remains we have, and are generally found on high ground, a hill-top being a favourite site. In dwelling upon sepulture, I trust to be able to show clearly that the burial of articles with the dead was not so much a religious act as a mark of respect to the dead. The archæological relics of Canada have never been fully described, and are deserving of a higher rank, in a scientific sense, than has as yet been accorded them. We have a grand field to work in, and the articles we find well repay us for the trouble taken. The aborigines of America are undoubtedly the fathers of smoking, and the elaborate workmanship which was bestowed upon their pipes shows the important place it took in their every-day life. There are no articles found which so well portray the aboriginal ingenuity as the pipes. Animals, birds, reptiles, and the human physiognomy are all carved upon the bowls and stems with life-like accurateness. Many specimens found would trouble a clever artisan of the present day to duplicate, allowing him all the modern tools to work with, because stones, tools, ornaments of various kinds, &c., were also manufactured with a precision simply perfect; and, strange to say, it seems to have been a matter of little moment whether they worked the hardest or softest qualities. Pottery, shell, and bone were extensively used in the manufacture of articles for their every-day life, whether for ornaments or necessary utensils; copper was also utilised to some extent, principally for tools, ornaments, and sword-blades; the ore was merely pounded into the required shape. Shells, which must have been brought a distance of nearly 2000 miles, are sometimes found in graves, evidencing the extraordinary fact that a trade must have been carried on between the aborigines of the north and those of the south, which, extending over such a vast distance, and with their primitive mode of travelling, must have made the articles exchanged of great value. The wampum was probably nearly altogether carved from these foreign shells.

Major J. W. Powell, U.S.A., read a paper on *The Classification of North American Languages*. Major Powell said that in his remarks he would confine himself to those languages which possessed at least a thousand words. Pointing to a map of the United States on which the distribution of the languages was marked, the speaker said that there were four great distinctive tongues on the continent, the Aligonquian, the Shoshonian, the Siouan, and the Athabascan. The classification of these languages was impossible, he said, but we could classify the arts, the habits, the philosophy of the peoples. He remarked on the fact that grammars and dictionaries, books, and even newspapers, were published in some of the Siouan languages, the Dakotan for instance. For the purpose of convenience and study of the North American languages, rules had been drawn up and adopted, which rules were read and commented upon by Major Powell. One of these was that family names should not be recognised if they consisted of more than one word, and another that all tribal names should terminate in "an," as Aligonquian and Sho-honian. These were highly necessary to prevent confusion. The speaker described the difficulty he had experienced in classifying the different names during the past fifteen years, and remarked that the affinities of various languages were not yet practically determined. Within a year, the work, he hoped, would be completed, as far as the United States were concerned, but it would take some years before the work for the North American continent was concluded. Four gentlemen were now in the field engaged in collecting vocabularies for this purpose. Remarking on the likeness between the words "kayak" and "caique," Major Powell said that it could be imagined how extremely difficult it was to decide upon such a matter, there being, for instance, eighty languages in North America which possess no affinities with each other. Grammatic affinities might exist, but none closer. He thought that early arts could not be relied upon to connect peoples. Institutions and languages were more valuable and lasting helps to classify nations, the latter especially so. Finally, the speaker said that, as there were eighty different stocks of languages and the same number of mythologies, it would be a long time before their labours were completed.

Mr. Rosefeldt observed that, although he had lived among the Indians for some years, he had never met with an Indian who could pronounce the letter R. In this they were like the Chinese, and therefore might have migrated into America by way of Behring Straits. He related an incident which occurred during his residence amongst the Indians. One of them asking him to what family he (the speaker) belonged, Mr. Rosefeldt replied, the fox, as this animal occurred in his coat-of-arms. The Indian said, "Then I must be your 'pickanniny,'" or son, showing the figure of a snake on his arm, "as the snake is the son of the fox!" This showed that the Indians imagined that they derived their descent from various animals.

Mrs. Erminie A. Smith read a paper *On the Customs and Language of the Iroquois*. Some years ago Mrs. Smith was received into the tribe of the Tuscaroras, and adopted as a sister by one of the chiefs of that nation. An assemblage was held to do honour to this auspicious event, and a handsome bead-work dress was prepared for Mrs. Smith. The chief who adopted her being one of the "Bear" family, she also became a Bear. Mrs. Smith made some interesting remarks upon the costumes and upon the gambling habits of the Indians, and showed some of the silver brooches used by them as stakes in the games. A hair "waterfall," composed of some five hundred scalps joined together, was exhibited, as well as the temperance banner of the Tuscaroras; this bore a rude representation of the American eagle destroying the demon of intemperance, with six stars of the six nations, and figures of the animals which are symbols of the tribes. Noticing the construction of the Iroquoian language, Mrs. Smith said that there were two so-called genders, noble and ignoble; the former comprised God, men, and angels, and the latter demons, the lower animals male and female, inanimate objects, and "women, children, and other chattels."

Mr. F. H. Cushing read a paper *On the Development of Industrial and Ornamental Art among the Zunis of New Mexico*. The speaker's remarks were illustrated by numerous specimens of pottery and other kinds of work done by the Indians. Mr. Cushing said that by adoption of the Zuni language, customs, habits of living, and costume, to the minutest particular, he had been enabled to obtain a vast amount of information regarding these people—descendants, as he said, of the "Pueblo Indians." The word "Pueblo," he explained, was applied to a nation who lived in communal dwellings. He brought forward evidence, linguistic and otherwise, to prove the descent of the Zunis from

these races. He described the causes that led to the architecture of the petty clans, such as a need of protection which induced them to seek the caves in cliffs, and traced the history of the "Pueblo" or communal dwellings. The art of pottery, he said, was practised in the "Pueblo" district to a very great extent. He gave an interesting account of the formation of the Zuni gourds, or water vessels, showing how they were covered with wickerwork in order to preserve them. Basket-work vessels were also used, these latter being covered with a preparation of clay in order to prevent the escape of the contents. Mineral coal was used in the manufacture of earthenware vessels and also upon the corrugated surface given to the bowls. A curious fact with regard to the food utensils of the Zunis was that they regard the bowls they make as possessing something in the nature of life or spirit. They place food and water near the vessel, and as a woman completes it she imagines she has made something like a created being. The different sounds made by the pots as they are struck, or as their contents boil, for instance, are believed to be the voices of the beings which are associated with the vessels. Apertures or blank spaces are left for the escape of this spirit. A Zuni woman, as she closes the apex of a pointed clay vessel, turns her eyes away, and says that it is "fearful" to watch this operation. She thinks that if she knowingly (that is in her sight) closes this orifice, which she regards as a source of life, the source of life in herself may be closed, and that she may be debarred from the privilege of child-bearing. Other evils are also expected to follow if she does not turn away as she completes the vessel's shape by closing the apex. The Zunis, in representing animals, always show a kind of line or passage leading from the throat to the heart, and cannot be induced to dispense with this line in any pictorial representation of animals. In conclusion, the reader of the paper referred to the probable origin of the shapes used in the pottery of America.

Dr. Daniel Wilson then read a paper on *The Huron-Iroquois, a Typical Race of American Aborigines.*—He remarked upon the natural boundaries of countries, and the difficulties they presented to nomadic races. East of the Rocky Mountains the ethnology was comparatively simple. There were but three great races or families, the Iroquois, the Algonquin, and the Athabascan. The Blackfeet were, however, a different race, and possessed different characteristics. West of the Rocky Mountains the subdivisions were more numerous, but not so large. He mentioned the valuable though imperfect vocabulary of Jacques Cartier, which showed something of the language used by the Iroquois or Six Nations. He enumerated the nations of which this confederation was composed, and remarked upon the localities in which they lived. The original native population of this part of Canada, Dr. Wilson said, was the Huron-Iroquois. They were found in the valley of the St. Lawrence by the early explorers. Some of them had been driven out and had returned to Canada at the time of the American Revolution, in one case, he said, bringing with them the silver communion service given to the Mohawk church by Queen Anne, and now used in the Tuscarora church. Dr. Wilson referred to the Indians of Lorette and of Anderdon as representing the ancient type of Hurons. These people, he said, believed that their ancestors came from the neighbourhood of the "great sea" or the Atlantic. The speaker then showed a skull, probably that of a Hochelaga Indian, which had been found near this spot. This, he said, presented all the types of the Huron race. He contended that it was a Huron people that had been found here by Jacques Cartier, though he said that the funeral customs of that nation did not seem to have been practised in this district. These funeral customs, and the ceremony of the "feast of the dead" were described in an interesting manner by the Professor. Dr. Wilson remarked upon the want of knowlege of metallurgy shown by the inhabitants of North America, and the general slow progress in civilisation which was displayed by these people. Copper in large quantities was ready to their hand, but no trace of its being used was found, and the application of fire to the metal seemed not to be thought of. He noticed the earth-works of the Ohio Valley, which he said should be visited by the British visitors before their return to Europe. He concluded by referring to the influence that the half breed population of Manitoba might have in future times upon the inhabitants.

Dr. Tylor, after expressing his thanks to Prof. Wilson for his communication, called upon Mr. Horatio Hale to make some remarks upon the subjects on which the last speaker had touched. This Mr. Hale did, saying that the tradition amongst the Hurons was that their ancestors had moved westward from the districts in which they were found by Cartier. With regard to the question of the language of the Hurons as compared with that of the Iroquois, Mr. Hale read a letter from the Hon. Judge Force, of Cincinnati, who had studied this subject. Mr. Hale also made some interesting observations on the difference of pronunciation between these people, his remarks being listened to with deep attention.

Prof. G. Lawson read a paper on *Food Plants used by the Indians.* The Professor began by remarking on the various berries that were found on this continent, as well as the numbers of nut-bearing trees. He showed that the wants of the aborigines would be supplied by the natural products of the woods and fields, and spoke particularly of the wild potato of Nova Scotia, which was so well known among the Indians. Other plants noticed were the bean, fields planted with this vegetable being found by Columbus and by Jacques Cartier, and maize, which was also much used. Beans were grown among the Indian corn, which formed the main crop. Evidence showed that plants like melons, pumpkins, and others of the same nature were cultivated by the Indians. Columbus, in 1492, found these plants surrounding Indian villages in such a condition as proved that they were cared for.

Lieut. A. W. Greely exhibited a collection of photographs of Esquimaux relics.

Lieut. P. H. Ray read a paper *On the Habits and Customs of the Inu of the Western Shore and Point Barrow.* Many of the natives had been measured, and it was found that the tallest height was 5 feet 10 inches, and the lowest 5 feet 1 inch. This was much higher than the natives of Greenland. Their powers of endurance were wonderful. Marriage laws they had none: the contract was severed at will. They never quarrelled or entered upon any controversy, and were extremely kind to their parents. Lieut. Ray described the manner in which these people prepared their food for travelling, and in which they captured the reindeer and the seal. Though they did not believe in a future existence, they were intensely superstitious, as Lieut. Ray found when he learned their language, and they paid great veneration to the oldest of their women. He thought these people the most primitive that white people had ever come in contact with.

Mr. R. Law read a paper by himself and Mr. J. Horsfall, *On Some Small Flint Implements found beneath Peat on Several Elevated Points of the Pennine Chain lying between Huddersfield and Oldham.*—Mr. Law introduced his subject by saying that, though perhaps of a local nature, it might be interesting. In the course of his paper he said that the flint implements which had been discovered had been submitted to competent authorities, and it was considered that they were the smallest ever discovered in England. They were supposed to have been carving implements, and some of them were not more than one inch in length and a quarter of an inch in breadth, while they were carefully marked and chipped on the edges. The speaker concluded by describing the moorland country and geological character of the soil in which these implements were found.

SCIENTIFIC SERIALS

THE *Journal of the Franklin Institute* for August contains:—Wire triangular truss, by Chas. J. Quetil, C. and M.E. (illustrated).—New British standard wire gauge.—Report on the trial of the "City of Fall River," by J. E. Sague, M.E., and J. B. Adger, M.E., with an introduction by Prof. R. H. Thurston (continued from vol. cxviii. p. 74, illustrated, and with a table).—Tests by hydrostatic pressure, by S. Loyd Wiegand, M.E.—Velocity of approach in weir computations, by A. W. Hunking and Frank S. Hart (with tables).—The earth's ellipticity, by L. D'Auria.—Suggestions for the improvement in the manufacture of glass, by George W. Holley.—Survey of the future water-supply of Philadelphia, by Rudolph Hering, C.E.—Influence of high pressure on living organisms.—Atmospheric changes at Nice.—Bernauf's telescope.—Microscopic organisms on the surface of coins.—Magnetism in Madagascar.—Selective absorption of solar energy.—Use of oxygen as a refrigerant.

Annalen der Physik und Chemie, No. 8, July 1.—On a new method of determining the vapour-densities of bodies with a low boiling-point, by Nik. von Klobukow (10 figures and a table).—On a new method of determining the vapour-densities of bodies with high boiling-points, by Nik. von Klobukow (7 figures).—On the influence of pressure on the viscosity of liquids, particularly of water, by W. C. Röntgen (2 figures and 2 tables).—On the

influence of density on the viscosity of dropping liquids, by E. Warburg and J. Sachs.—On the conductibility of heat of tourmaline, by Franz Stenger (2 figures).—The expansion of crystals by heat, by Eug. Blasius (3 figures).—On the passage of electricity in gas, by F. Narr (with tables).—Remarks on the resistance box of Siemens and Halske, by E. Dorn (4 figures).—On the known dichromatic colour-systems, by Arthur König (1 figure).—On the sensibility of normal eyes for the perception of light of long wave-length, by Arthur König and Conrad Dieterici (1 figure and tables).—Metallic and total reflection of isotropic media explained by means of Neumann's system, by E. Ketteler.—Experimental determination of the wave-length of the invisible prismatic spectrum, by S. P. Langley (5 figures and table).—Demonstration research on the relation between light polarised by reflection and by refraction, by G. Krebs (4 figures).—On a freezing apparatus, by E. Lommel (1 figure).

Journal de Physique théorique et appliquée, August.—On the electric conductibility of very weak saline solutions, by M. E. Bouty (7 parts, 30 pages, with figures and tables).—The influence of heat and magnetism on the electrical resistance of bismuth, by M. A. Righi.—Variation in the physical properties of bismuth placed in a magnetic field, by M. Hurion.—Variation of the resistance of bismuth and some alloys with the temperature, by M. A. Leduc.—On some experiments illustrating an explanation of Hall's phenomenon, by Shelford Bidwell.—Note on Hall's phenomenon, by Herbert Tomlinson.—The explosive wave, by MM. Berthelot and Vieille.—Researches on the compressibility of gases, by E. H. Amagat.—Memoir on the compressibility of air and carbonic acid at 1, 8, and from 20 to 300 atmospheres, by E. H. Amagat.—On a new form of the relation $F(pvt) = 0$, relating to gases, and on the law of the expansion of these bodies at constant volume, by E. H. Amagat.

SOCIETIES AND ACADEMIES

Sydney

Royal Society of New South Wales, August 6.—H. C. Russell, B.A., President, in the chair.—Four new members were elected. Donations received consisted of 327 vols. and pamphlets, forty-six anthropological photographs, and a collection of fossils.—A paper was read by Mr. Lawrence Hargrave on the trochoided plane. The paper was explanatory of some models of animal progression exhibited by the author before the Society, and gave in detail the opinions and deductions he had formed from his observations of the natural motions of animals. The author was of opinion that there was evidence to show that Nature almost universally used the trochoided plane for the transmission of force, and that its use by man opened up a wide field for engineers; he asked the opinion of the members whether there were grounds for believing that the trochoided plane was a distinct mechanical power, and if not under what head they classed it.

Paris

Academy of Sciences, September 29.—M. Rolland, President, in the chair.—Remarks in connection with a work "On the Origin of the Earth," presented to the Academy by M. Faye. The book is described as mainly historical, recording the various theories on the cosmogony of the universe that have prevailed from primitive times down to the present day.—Observations on a preceding communication dealing with the theory of the form of the planets, by M. F. Tisserand.—On the vegetation of the Amaranthaceæ: distribution of the fundamental substances amongst the various parts of this family of plants and its congeners at the various periods of their growth, by MM. Berthelot and André.—A simple process for effecting the separation of cerium and thorium from mixtures in which these elements are found, by M. Lecoq de Boisbaudran.—On the solubility of the prussiate of gallium; rectification of a previous communication by M. Lecoq de Boisbaudran.—On the trinomial linear equation in matrices of any order, by Prof. Sylvester.—Report of the Commissioners, MM. Bouley, Bert, Gosselin, Marey, Pasteur, Vulpian, and Richet, on various communications touching the treatment of cholera. Of the eight communications received since the last report, five are undeserving of mention. The three others are rather theoretical than practical, and that of Dr. Pereda y Sanchez alone seems to contain a few suggestions worthy of further consideration.—On the second experiment made by MM. Tissandier brothers to propel a screw balloon by means of electricity, by M. G. Tissandier. This trial, made on September 26 at Auteuil with improved appliances, yielded all the results that could be expected from a balloon constructed with an exclusive view to experimental study. The vessel proved perfectly stable, obeying every movement of the rudder, and enabling the aëronauts to execute numerous manœuvres in various directions above Paris.—Observations of Barnard's comet and of Luther's planet made at the Observatory of Nice, by M. Perrotin.—Observations of Wolf's comet made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—Observations of the same comet made at the Paris Observatory (equatorial *coudé*), by M. Périgaud.—Observations of the same comet made on September 21 at the Observatory of Bordeaux with the meridian circle, by M. Courty.—Note on the group of points in involution marked on a surface, by M. Le Paige.—Description of a new polarising prism presenting some advantages over those of Nicol and of Hartnack and Prazmowski, by M. E. Bertrand.—Note on the products obtained from tellurium acted on by nitric acid, by MM. D. Klein and J. Morel.—On the employment of the sulphate of copper (blue vitriol) for the destruction of mildew, by M. Ad. Perrey. Vines recently treated with this solution in the department of Saône-et-Loire were everywhere distinguished from the surrounding plants by the bright green colour and healthy appearance of their foliage. But this remedy seems to be efficacious only in the case of young vines from four to six years old.—Report on the present climatic conditions and sanitary state of the isthmus of Panama, by M. R. Regnier. The prevailing notions regarding the insalubrity of this region appear to be unfounded. Its temperature varies from 24° to 30° C. in winter, rising to 35° in summer. The climate is hot and moist, with two seasons, summer and winter, the latter being the rainy season and the shorter of the two. Although the climate does not produce the same depressing effect on Europeans as many other tropical countries, certain hygienic precautions should be taken and scrupulously observed. Two large hospitals, one at Panama, the other at Colon, have been erected for the treatment of the men at present employed in the construction of the canal. A health resort has also been established at Taboga, and these various measures are stated to have reduced the mortality almost to a lower rate than in many great centres of industry. It is at present about 2·5 per cent., a proportion not exceeding the average of European countries.

HANDBOOK OF BOTANY

Handbuch der Botanik. I. and II. Herausgegeben von Dr. A. Schenk. (Breslau: Verlag von Eduard Trewendt, 1879-1882.)

As early as 1861 it had become apparent to certain leading German botanists that the limits of their science had been so far extended as to make it impossible for one writer to treat the whole subject with such uniformity and thoroughness as is required in the composition of a standard text-book, including the substance of the facts well ascertained up to the date of its issue. Accordingly Hofmeister, with the assistance of others, and especially of Sachs and De Bary, planned a joint "Handbook of Physiological Botany," and though, owing to the difficulties which are always liable to attend joint authorship, the parts written by the several contributors were issued at various dates from 1865 to 1877; and though some of the parts included in the original scheme never appeared at all, those published are together the result of the most considerable attempt hitherto made to issue a comprehensive and standard Text-book of Physiological Botany. During the twenty years which have followed the adoption of this plan by Hofmeister and his colleagues unprecedented advance has been made in the science, and it is thus still more necessary than before that the task of authorship of a comprehensive handbook should be divided. The "Handbook of Botany," which is in course of issue by Prof. Schenk, and of which two volumes are already complete, is a second attempt, somewhat similar in idea to that of Hofmeister, though differing from it in many points. The staff of authors is larger, and since the space allotted to the several authors is less, greater uniformity in date of issue has been attained; there is, however, in Schenk's "Handbook" no prearranged and well-balanced plan of the ground to be covered, or at least the first two volumes give no clue to any such plan. Each article appears to be independent of its neighbours, and must be regarded as a separate essay on a definitely circumscribed, and in some cases a very limited, branch of the science. Since this is the case, it is clear that the "Handbook" cannot be used by beginners as a text-book of the science; it is suited rather to specialists, and others who may desire special information on the subjects which are treated. To these the book will be of the greatest use and interest, since the articles are written by well-known men, who have made the subjects of their essays their special study.

It will be impossible here to discuss each of the articles in detail, nor indeed will it be necessary to do so, since in more cases than one the articles are in the main useful epitomes of more extended works already well known to the public; in other cases, however, the articles are the result of fresh constructive work. While those of the former category will be merely named, those of the latter order demand more careful attention.

The first article, entitled "Die Wechselbeziehungen zwischen den Blumen und ihre Kreuzung vermittelnden Insekten," is by Dr. Hermann Müller, whose name will be sufficient guarantee of its excellence; while it is written in such a style as to interest those who have not made botany their special study. It is followed by a short article by Prof. Drude on Insectivorous Plants. The essay on the Vascular Cryptogams, by Dr. Sadebeck, is one of the most important of the whole series: the author gives a concise account of the chief facts hitherto ascertained, and has arranged them on a plan which is well suited to their comparative treatment. After a short general description of the cycle of life as found in these plants, he treats in the first section of the spore, germination, the prothallus with the sexual organs, and the embryo; while the second section is devoted to the vegetative organs and the sporangia. Each organ is described successively, as far as it is known, in the various forms of vascular Cryptogams, and thus the comparison of details of structure and development of each organ in various groups is made more easy than is usually the case in other works. Then follows an article by Prof. Frank under the heading "Die Pflanzenkrankheiten"; this may be regarded as a useful abstract of his more extended work on the same subject, which is already well known to botanists. The first volume is brought to a conclusion by an article on the Morphology of Phanerogams, by Prof. Drude. It has been the object of the author to furnish a compendium of the external conformation of flowering plants, and their sexual organs, reference being made to their comparative anatomy and development. At the present day this object is in itself unsatisfactory: to gain a true insight into the morphology of Phanerogams reference must necessarily be made to the lower forms, and the want of such reference and comparison is apparent throughout this article, especially in that part of it which is devoted to the morphology of the flower.

The second volume includes, in the first place, a treatise on Vegetable Physiology, by Detmer, which has laboured under the disadvantage of being published almost simultaneously with the excellent lectures of Prof. Sachs on the same subject. It is followed by Falkenberg's essay, headed "Die Algen im weitesten Sinne," which is one of the most important of the whole series. In the introduction he shows how the classification of the Thallophytes proposed by Cohn in 1872, and adopted by Sachs, led the way to the system of classification proposed by De Bary for the Fungi; this writer, after excluding the Myxomycetes and Schizomycetes, recognises that the various remaining groups of Fungi may be regarded according to their morphological characters as a natural series. Falkenberg treats the Algæ in a similar way; he strips off from the whole series of chlorophyll-containing Thallophytes (to which the term Algæ in its widest sense may be applied) certain outlying groups, viz. the Diatomaceæ, Schizophyceæ, and Florideæ; the remaining Chlorophyceæ and Melanophyceæ together form that series which he terms the *Algæ in the narrower sense.* Adopting this general method, the author has constructed a compendious description of the whole series of Algæ, which will well repay those who read it. The essay on the Muscineæ, by Goebel, is written in a similar spirit to that of the article which precedes it, and can be well recommended as giving the best concise account of the morphology and development of that class hitherto published. The article by Prof. Pfitzer on the Diatomaceæ will be welcomed, as

giving in an accessible form a detailed account of the structure of these plants from the pen of one who has already distinguished himself in this field. The second volume is brought to a close by a treatise by Haberlandt named "Die physiologischen Leistungen der Pflanzengewebe," a subject well suited to one of the Schwendenerian school, to which its author belongs. Anatomical facts, many of which are already well known, are here placed before the reader in the light of the anatomico-physiological method, which the pupils of Schwendener claim as having been initiated by him in 1874.

From what has been already said, it is clear that this "Handbook" will, by the individual worth of many of its articles, take a prominent place among standard botanical works, and will undoubtedly be of great service to advanced students. Further volumes are still in progress, and the appearance of their successive numbers will be looked forward to with interest. F. O. B.

OUR BOOK SHELF

A Synopsis of the British Mosses. By C. P. Hobkirk, F.L.S. Second Edition. 8vo, 240 pages. (London: L. Reeve and Co., 1884.)

THIS is a new edition of a work that appeared originally in 1873. There is no other recent handbook of British mosses, so that it has had the field entirely to itself, and has had a large circulation amongst our home collectors. It is a cheap working handbook, something on the scale of Babington's "Manual of the British Flowering Plants and Ferns," without any figures, but with full diagnostic characters of all the indigenous genera and species. Britain is exceptionally rich in mosses, and in this new edition 129 genera and 576 species are enumerated and described, with a short notice of locality.

Mr. Hobkirk is well known as an excellent practical bryologist of many years' experience. He has not attempted either in this or the previous edition to introduce any novelty in classification. In the first edition he followed Wilson closely, and Wilson in his turn deviated but little in arrangement, nomenclature, and the circumscription of genera and species from the great standard work on the mosses of the whole of Europe, the magnificent "Bryologia Europea" of Bruch and Schimper, which contains elaborate figures of every known species. In this second edition Mr. Hobkirk has altered his classification to correspond with that of Jaeger's "Adumbratio Muscorum," a change which we consider of very doubtful utility, as it has the effect of making the preliminary synopsis much more elaborate and more difficult for a beginner to understand and use.

An illustrated work on British mosses brought up to the standard of Bruch and Schimper has been greatly wanted. Now, Dr. Braithwaite is bringing out in parts a work of this character, with admirable original drawings and detailed descriptions. At the present time this is about one-third completed, and it is greatly to be hoped he may have health and strength to finish it. For any one needing a cheap working handbook we can cordially recommend the present book. It contains a brief glossary of terms. Only the names that are adopted are given, without any synonyms. One fault in the preliminary key that will puzzle a beginner is the want of definitions for the two primary divisions—Saccomitria and Stegomitria. Another point that without explanation will likely puzzle students is that the authorities cited for each species are those of the author who first used the specific name, taken quite independently of the genus under which it is now placed, so that, for instance, Linnæus is cited as the authority for *Eucladium verticillatum*, when the genus Eucladium was first characterised by Bruch and Schimper half a century after Linnæus died. The orthodox plan is to cite the authority for genus and species combined.

J. G. BAKER

Our Insect Allies. By Theodore Wood. 8vo, pp. 1-238. (London: Society for Promoting Christian Knowledge, 1884.)

WRITERS on popular entomology are hard driven nowaday to find titles for their works, or subjects that have not already been worn to shreds by previous authors. To be successful they must possess the same talent that enables a *chef-de-cuisine* to contrive an *entrée* from the same materials, so disguised by name and sauces as to lead his patrons to consider they are partaking of a new dish. The author of this nicely got up little book has evidently felt himself in such a position, but on the whole he has succeeded very well, the more so because there are fewer errors than ordinarily exist in popular entomological works. He takes as his standpoint the fact that very many insects are indisputably serviceable: some by ridding the world of putrid or unhealthy organic matters, both animal and vegetable; some by destroying other insects undoubtedly noxious. The result is that we get here a series of histories of individuals or groups detailed in popular language, often from personal observation, and for the most part well illustrated by woodcuts. The author evidently feels himself most at home in dealing with the *Coleoptera*, and, as we think, judiciously takes up the position that bark-beetles and wood-borers are scavengers, seeking to devour what is already morbid, and are not the *cause* of decay in the trees in which they are found. We fail to follow his account of the mechanism by which the click-beetles (p. 207) perform that acrobatic movement so familiar to our childhood in the shape of the "jumping frog"; to our mind the "mucro" that is the chief agent in this action is not "elastic." Why are the *Aphis*-parasites known as *Aphidius* stated to be *Chalcididæ* (p. 168)? Why is a *Syrphus* larva figured (p 160) as that of a "Golden-Eye," or "Lace-Wing"? The introductory remarks and the concluding notes contain some very judicious reasoning on the aim and purpose of entomological studies, and we sincerely wish we could agree with the author (p. 236) that collectors, as opposed to students, are "now in a very small minority"; a vast improvement towards this end has undoubtedly taken place latterly, but the time for congratulation has not yet arrived. The Society under whose auspices this little book is published has done much towards popularising natural history in this country; this work may be classed amongst the best of the series, and no doubt in a second edition the author will revise it and rectify a few palpable errors.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Shifting of the Earth's Axis

HAVING quoted the Greenwich observations so often, and with all respect, during the last twenty years, in my several Great-Pyramid publications, as showing that there is a slow shifting of the earth's axis going on, with the effect of altering the latitude of places minutely from age to age (see more especially p. 81 of fourth edition of "Our Inheritance in the Great Pyramid"), I cannot remain unconcerned when the present energetic Astronomer-Royal comes out so very positively with the statement that the Greenwich observations of the last forty-seven years (which he confines himself to) show nothing of the kind, and that there is no such movement of the earth's axis going on.

At least so I understand his letter in NATURE, vol. xxx. p. 536. If that statement or conclusion is perfectly correct, I must of course allude to it in the next edition of my Pyramid book, and adopt its corrections, whatever they may lead to; so that it is well at once to ask any further questions which seem demanded for full trust and credibility.

That the observations made at Greenwich during the last forty-seven years, when computed as the said Astronomer-Royal has computed them, do not show any change of latitude during that space of time, no one is more ready to allow most honourably than myself. But before we can admit that that result, pure and simple, absolutely establishes the non-shifting of the earth's axis of rotation, two more things at least must come about, viz. :—

First, the Astronomer-Royal must attack and demolish the observations and calculations made at the great Russian Observatory of Pulkowa, which show that such a change, at the rate of about one foot *per annum*, has been going on through the last quarter of a century, and are even believed in America to be more accurate than the Greenwich observations. And

Second, he must take up, and similarly destroy, the testimony of the earlier Greenwich observations themselves, before these last forty-seven years of his own computation began.

Now those earlier Greenwich observations were so remarkable for what they did indicate in their own time, that I may freely mention now, seeing that all the parties are dead, that somewhere about 1836, Sir Thomas, then Mr. Maclear, at the Royal Observatory, Cape of Good Hope, received a private letter from Thomas Glanville Taylor, Honourable East India Company's Astronomer at Madras—and earlier an assistant at the Royal Observatory, Greenwich—stating his belief that the latitude of the British National Observatory was continually decreasing; and he gave a list of latitudes, as determined by Greenwich observations, so far back as they went, but condensed into three epochs, to prove the point.

The matter was kindly communicated to me by my then chief, Sir Thomas Maclear, and was of course deemed interesting and curious at the time; but had quite gone to rest in my mind, until twenty-nine years afterwards, when I fell across the same effect, in the same direction and at nearly the same rate, but through a longer period of time and to a much larger accumulated quantity, at the Great Pyramid of Geezeh in Egypt. The datum fo the latitude of 4000 years ago, to compare with the present observed latitude of the same spot—though exactly that which the learned Dr. Hook desired so much, but in vain, to find anywhere 200 years ago—is not perhaps so purely and perfectly scientific as the high-class practical astronomers of our times will always condescend to notice. But in the accompanying feature of change of azimuth, so creditably brought to the front by Mr. Flinders Petrie, there is a testimony of modern observation to ancient accuracy of so respectable a character—if I may be allowed so to say—that it ought not to be entirely ignored; and it was first mentioned thus.

While I was at the Great Pyramid in 1865, and just after I had there measured the azimuths of the entrance-passages of the Great and Second Pyramids on successive evenings by reference to the six-hour elongations of Polaris, there came a letter from a retired civil engineer in Edinburgh, a man of long Batavian experience in his day, and gifted with remarkable powers of modern science and originality of mind,—in which letter he was pleased to run down all the presumed object of my work out there on the Geezeh Hill. Especially too was he pungent on the point that even the best of the ancients had not that triumph of modern civilisation, "the manufacturing principle," in them; "for," said he, "they could not make two things alike."

Whereupon I sent him the azimuths of the entrance-passages of those two grand pyramids, so many hundred feet apart, and pointed out, that, though they showed an error of azimuth for modern date of nearly five minutes, yet the one pyramid exhibited so very nearly the same identical quantity as the other,—that they were, angularly, nearer together, or more exactly alike, than were the two halves of one and the same azimuth circle I was observing with. And yet that circle was by so celebrated a maker of modern times as Troughton, and the instrument a choice one specially made by him to be presented to the celebrated Prof. Playfair, by his admiring students in the University of Edinburgh; and by Playfair's executors, again, presented after his death to the Royal Observatory, Edinburgh, where it is still preserved in honour.

The Sky-Glows

IN reply to Mr. Backhouse's question (p. 511) as to where the context of Mr. Neison's remarks can be seen, I can only say that I do not know. I came across the portion quoted relating to these phenomena at the end of the Astronomer-Royal's Report upon the Weather of 1883. Like Mr. Backhouse, I have been on the look-out for solar halos, or big rings round the sun as we call them, for the last thirty years, more with a view to be prepared for squalls, &c., when boating, than anything else. But for some years there has been so much haze about the sun, and the weather has so often cried "Wolf," so to speak, with no responding gale or squall, that of late I have ceased to take much note of such warnings. I may here mention that the rosy corona, when visible, as it so often is now, can be well seen by looking towards the place of the sun, but standing in the shadow of some high building; or at times by totally eclipsing the sun with a hat held between him and the eye.

As far back as January 1, 1884, in a letter to the *St. James's Gazette*, I ventured to predict that we had not seen the last of what were then spoken of as the "Recent Sunsets"; there was a very remarkable after-glow ten days after this, reaching the zenith, seen even in London. In the same letter of January 1, I suggested some increase in solar energy as the cause of these phenomena.

For some time, though feebler repetitions of the glows continued to be seen up to the end of March, there was nothing strong enough in the way of colour worth noting. But from what I continued to see in the shape of vapour, together with that strange warm colour by day about the sun, I felt sure that whatever might be the cause of these phenomena must still be going on, and in a short note dated April 12, I again spoke of their probable early reappearance. A graphic account of these after-glows, written by an observer at Smyrna, appeared in the *St. James's Gazette* of February 25, in which he pointed out what I have often since noticed, viz. that with excess of moisture all colour disappears.

This was at times very remarkable in the early part of July this year, when we had some of the strangest white sunsets I have ever seen. The sky around and above where the sun had set, looking almost ceiling-like in its opacity, upon which soon appeared numbers of weird small cloud forms, at times very regular, like ripple-marks in sand, or the bones of some great fish or saurian embedded on a slab of stone.

Against these pale sunsets all buildings and trees told like black velvet, while the clouds would rest almost stationary for a long time. Years back such a sky would have betokened a hurricane; but evening after evening they were repeated, and no storm of any importance followed. For many years past, but notably during the summer of 1883, I had observed a steady increase in a white luminous glare about the sun, so much so that I wrote about it in the year 1882 to my brother in India. I was not therefore surprised altogether when as the sunsets increased in colour, which they mostly do in autumn, that this glare last winter was followed by something more than usual in the way of colour; and here I should like to say that, as far as I have seen, and I have missed very few chances of watching them, that though last winter twilights often increased up to a certain time in strength, yet they did not exceed in duration the time allotted to twilight in the almanacs. This letter is already too long, but I cannot help asking, in conclusion, whether it may not be possible that we have been all along muddling up cause and effect, and that the eruption at Krakatoa, the recent earthquakes and waves, as well as the strange atmospheric phenomena, which are still about us, cannot all be traced to one cause, viz. actual increase of sun power?

Southampton ROBERT LESLIE

THIS evening after sunset I noticed a column of yellowish light over where the sun had set, and moving with the sun. I have seen the same before. Can it be the zodiacal light? I have frequently noticed during the present year, while the sun was much too high for any sunset colours, a pinkish colour in the sky. This has been observed by others, but I do not know whether it has been seen outside the British Islands. It must be connected with the sunset-glows which several of your correspondents have described.

JOSEPH JOHN MURPHY

Belfast, October 12

Circular Rainbow

In the notice given in Nature (Sept. 11, p. 465) of the beautiful circular rainbow that is seen in the spray of the Montmorenci Falls near Quebec, the expression in the heading, "seen from a hill-top" will convey an erroneous idea without some explanation. The complete circle is only seen by getting down in the spray to the edge of the low rocks, within a few inches of the level of the water, and the circular bow then passes down to the feet on each side; it is indeed most perfectly seen by turning round and stooping down to look back between the legs, when the complete circle is seen without interruption from the feet. The bow is small in diameter, and is a narrow band, appearing nearer to the eye than an ordinary spray rainbow. I had the pleasure of seeing it on August 25, on the occasion of the British Association Canadian visit. William P. Marshall

To Find the Cube of any Number by Construction

Prof. Karl Pearson has kindly referred me for a *simple* graphical construction for any positive or negative power of any rational quantity whatever to Egger's "Grundzüge einer graphischen Arithmetik." This method, he informs me, is reproduced in Cremona's "Il calcolo graphico." I was of course aware that there were several simple constructions. I was induced to write upon the subject owing to the unexpected discovery that there was a line in the geometry of the triangle which enabled one to obtain the cube of a number.

October 14 R. Tucker

EXPLORATIONS IN ICELAND[1]

The Lava Desert of Ódáðahraun

On July 25 we set out for the southern Dyngjufjöll, in order to examine Askja. All previous explorers of that volcanic locality have taken the northern route from Svartárkot, but no one has hitherto approached it from the east, from Herðubreið, any advance from that side having been deemed impracticable. This I wanted to test for myself, and shaped my course from the tent (pitched, as before said, to the south of Herðubreið) in a direct line on the wide gap that opens in Askja to the east. The whole intervening country was one continuous succession of lavas, so effectively covered with pumice and scoriæ from the great explosion of 1875, fortunately for us, that the whole was really one scoriac plain, the pumice boulders measuring generally one to two cubic feet, some more, some less. If it had not been for this scoriaceous cover, these lavas would have proved pretty certainly utterly impassable for horses. We took good care to keep to the crests of the thickest pumice-drifts, and though such travelling is rough enough for horses, yet they sustain no great harm, because the pumice is so light and brittle. Under the south-eastern spurs of Dyngjufjöll we came upon a lake, shallow, but of considerable magnitude, of the existence of which there was no previous knowledge. About midway between Herðubreið and Dyngjufjöll the country begins to rise up towards the aforementioned gap in Askja. Askja is a cauldron-shaped valley in the centre of Dyngjufjöll, which is an enormous complex of mountains 4500 feet high. This valley contains innumerable craters which have erupted at various periods; the sides of this valley rise to between 700 and 800 feet, but out of the aforementioned gap lavas have flowed over the lower country outside all the way down to Ódáðahraun, forming an enormous oval of an average incline of 4° 33′. When we came close up to the gap, the scoriæ ceased, and at once the lava became exceedingly difficult to pass. But by aid of frozen snowdrifts filling dips and dints in the slopes, we managed to thread our way along, and thus actually to get into the valley; only one single tongue of lava we had to cross without the aid of snowdrifts—one which, though very narrow, we had the greatest difficulty in getting our ponies over. Having at last succeeded in this, we rode along frozen snowdrifts under the southern slopes of the Askja valley, and thus reached actually on horseback the craters which exploded here in 1875. Previous visitors to Askja have entered the valley through a pass in the mountains inclosing the valley from the north, outside which pass they have had to abandon their horses and to reach the craters on foot over an almost impassable lava-stretch in the bottom of the valley, taking four to five hours in passing the distance from the pass to the craters. From our tent by Lindaá it took us nine hours to reach the craters, but the return route we accomplished in seven. We now left our ponies provided with their fodder beside the large eruptor of 1875, and set off on foot to examine the locality in every direction, spending for that purpose the whole of the bright night and a portion of the next day. So over-covered was Askja with snow that journeying along here was like journeying in the heart of winter. The whole mass of Dyngjufjöll is made up of palagonite breccia interspersed with layers of basalt. Into this mass Askja sinks in the shape of a shallow basin, and may derive its present form partly from certain stretches of it having sunk down in consequence of eruptions, partly from that natural dint or basin-formation of valleys which is so strikingly common to tufa mountains in Iceland. But the supposition that the whole of this valley, about sixteen square miles English, is one crater, the result of one great volcanic explosion, is unwarranted. In the great eruption of 1875 a very considerable extent of ground "fell in" in the south-eastern corner of the Askja valley round the craters, and the vertical precipice of the fractured crust of the earth on the side of the Askja valley measures, according to Prof. Johnstrup's survey, 740 Danish feet; that at the opposite side in the mountains is at least double in thickness. The vertical walls of the precipices exhibit in a clear manner the successive layers of lava which fill the bottom of the Askja valley. In the earth-slip thus created there was, in 1876, a small lake of dull-green colour, circular, and measuring about 4000 feet in diameter. This lake now fills the whole bottom of the slip and measures 10,000 feet in length. In 1876 the temperature of the water was 22° Celsius (71°·6 F.), but has now fallen to 14° C. (57°·2 F.). The crater, which by its explosion covered the east country with pumice and scoriæ in 1875, is situated in the north-eastern brim of the fissure, and is 300 feet in diameter and 150 feet deep; its outer circumference flat, and built up of scoriac ashes, its inside cylindric and perpendicular. In 1876 this crater only emitted steam, now it has turned into a boiling cauldron of clay, the clay mud at the bottom being gray with an admixture of bluish green tint, boiling and wallopping incessantly; through the south-eastern part of its bottom there issues by a subterranean vent a thick column of steam with loud roars and reports, and all around this column smaller fissures issue thinner jets of steam and fumes. Interspersed with the scoriæ in Askja and on the eastern side of the surrounding mountains are found small glazed grayish-blue pieces of trachyte thus formed by the last eruption: among these there are some found of which one-half, or a portion, is reduced to pumice, while the remainder retains its trachytic constituency. In the south-eastern corner of the dip right up from the water are also found a number of craters from which radiate rents and gulfs honeycombed with innumerable fumaroles and crater-tubes from which clouds of steam roll up high above the crests of the mountains, the roar and boom from which are heard to a great distance, resembling the rumbling sound of steam let off from many boilers at once. Deposits of sulphur are already visible round a number of the fumaroles, and yellow-green patches of sulphur show all about the precipices, where every chink and rupture lets off sulphurous fumes. In the eastern part of the slip the scoriaceous layers

[1] Continued from p. 565.

have recently been rent asunder by a rift 150 to 200 feet deep, reaching from the summit of the mountain all the way down to the water. Across this rift there is no way of passing, and, in order to reach the south-eastern corner of the slip, it is necessary to scramble up to the top of the mountain, so as to get round the crevasse. It is difficult to form any adequate conception of the titanic grandeur of Nature at this spot. He who has once had the opportunity of viewing it from the precipice of the earth-slip will never forget the impression. Having finished my survey here, we returned to our tent the same way we had come, glad of rest, exhausted with fatigue and want of sleep as we were, after thirty-six hours' continuous travel.

On July 28 I set out on my return journey to Mývatn, taking a direct course across the northern part of Ódáðahraun to the farmstead of Grænavatn, on the southern side of the lake (Mývatn). This I did with a view to rediscovering the whole of the old highway, the eastern end of which I had already traced. First we shaped our course directly for the northern end of Herðubreiðarfjöll, guided by the beacons to which I have alluded already. We crossed a pass, dividing the easternmost neck of the mountains from the main range, in the eastern approach to which an excessively rough lava, split by innumerable rifts, had to be traversed, in which we succeeded by the mode of scrambling. On the verge of one of the rifts in this lava we came upon a dilapidated beacon, and again upon another on the western defile from the pass, from where we threaded our way along the skirts of a recent and very rough lava, directing our course for the central neck of Herðubreiðarfjöll. Here we were intercepted by two enormous rifts, 100 to 150 feet deep, divided by an earth-slip one mile broad, and twenty miles long. With the exception of Almannagjá and Hrafnagjá, near Thingvellir, these are the largest rifts in Iceland. Having succeeded in bringing our caravan over the eastern brim down alongside the spurs of an isolated "fell," we charged the western brim in vain for a long time until we came upon a sort of steep pass, up through which we brought our ponies, and found upon the verge three dilapidated beacons, which showed that we were still on the traces of the old highway. From this spot beacons may be still traced in a straight direction for Fremri Námur, but recent rifts and lavas have destroyed the road, which, though I now knew its direction, I could pursue no farther. Here, namely, we thought we had overcome all difficulties, but found soon to our cost that we were mistaken. Some distance to the east of Fremri Námur there is a quite recent-looking lava, very long, but narrow, which evidently has welled out of a lava fissure here in 1875, when, besides Askja, Mývatnsöræfi also were in a state of volcanic activity. This lava is not connected with the well-known more northerly lavas of 1875, wherefore its existence has been overlooked hitherto; and when Johnstrup constructed his map of the lava of Mývatnsöræfi, he was not aware of the fact that the same rift which gave birth to the northern lavas of 1875 had, further to the south, given existence to this, which measures fully one-half of the others. To the east of this lava the earth is all cut up by bottomless cracks, over which it was truly a breakneck business to pass. Across some we had to urge our ponies to jump, others we passed by means of natural bridges of loose boulders, which frequently gave way. This was travelling with one's life in one's hand, and to me it is the greatest wonder that no harm resulted to man or beast. To attempt crossing this new lava was entirely out of the question, so we had to bend our way southward along its eastern skirts until we might get round its southern spur. At this end of the lava I observed a peculiar rift not more than thirty to forty feet long and three to four inches broad, on which twelve craters were situated, in every way formed and shaped as large craters are generally, but of such miniature dimensions, that they looked as if they had been intended for toys for children; the aperture of most of them was only four to five inches in diameter, that of the largest two feet. These had, however, squirted forth dashes of lava to the distance of sixty feet. When at last we had reached the southern end of the lava, a new trouble intervened in the shape of what appeared to be an endless rift, and utterly impassable. We had therefore to make up our minds to spending the night, or whatever time might be required, in finding a passage across this barrier; and after five hours' weary struggle we at last managed to scramble across where the main crack split up into smaller ones. This was hard work for our ponies, languishing with thirst and with hardly anything to eat; and perhaps only a degree less arduous for us, who in the matter of food and drink were no better off. Having crossed this serious barrier, we came upon a much more even tract of lava, and presently, to our intense relief, struck a pool of water under a snowdrift in a dent in the lava, where, having watered our horses, we treated them to the last scanty remainder of their fodder, and then went on our way. In the early morning we reached the valley called Heilagsdalr in Bláfjöll, where we were obliged to pitch our tent in order to give the exhausted animals the benefit of the scanty pasture which a few plots of grass offered. After a few hours' welcome sleep we broke up hastily, a gale of wind with rain and sand-drift having burst upon us in the meanwhile. Our course now lay across the spurs radiating to the eastward from Bláfjöll, but such was the violence of the hurricane that it was well nigh impossible to sit on horseback without being blown away, and equally difficult to guard against the despairing animals being blown out of our hands into the howling wilderness. After some really considerable trouble and hardship, we managed to scramble down a precipitous gorge into the upland plateau on which the Lake of Mývatn has found its bed. After having more than once lost our bearings on these lower lava wilds, we succeeded at last in striking the homestead of Grænavatn, exhausted with our exertions, and were glad of a grateful rest in good beds, after having spent a fortnight in a tent, with our saddles for pillows.

TH. THORODDSEN

Reykjahlíð, near Mývatn, August 4

STORAGE BATTERIES

THE importance and desirability of an efficient and economical storage battery have been very widely recognised, but it is at the present time pretty generally felt that no existing form of storage battery is perfect, and that they are on the whole extravagant and wasteful to an extent sufficient to more than compensate for their undeniable convenience. It is perfectly certain that their employment has not become at all general, and that they have failed to realise the somewhat sanguine hopes of their early promoters.

It seems worth while to examine into the causes of this partial failure, and to inquire how far the evil opinion held by many practical men concerning our present method of storing electrical energy is justifiable.

One of the main objections is that storage involves a loss of some 50 per cent. of the whole. Now all methods of storing and transmitting energy involve some loss. To say that any particular method involves a loss of 50 or even 90 per cent. is not to condemn it utterly. There are many cases when the convenience of storage outweighs the evil of waste altogether; three principal ones may be specified.

(1) When the power of the source would be otherwise so completely wasted that every fraction of it stored is clear gain. This is the case of much terrestrial water power. The energy of the tides or of Niagara is enormous, and wholly wasted so far as human activity is con-

cerned; if 50 or even 10 per cent. could be stored in such a way as to be conveniently available, it would be of considerable value, and any arrangement capable of effecting this storage could only with injustice be stigmatised as wasteful. The solar energy of the Carboniferous epoch has most of it been wasted; but a small fraction—probably not a millionth per cent.—has been saved and stored in the Coal-measures. It is possible to abuse the coal for not having stored more, but we find it a useful modicum nevertheless.

(2) A second case when the advantage of storage overbalances the loss is when regularity and continuity of supply is needed, and when the source is irregular and fitful. Wind and wave power illustrate this kind of source; it is manifest that wind power has not been so largely used as it would have been, had it been steady and dependable. A practicable method of storing up its energy and giving it out as wanted would gradually cause it to be very largely employed. This case is also illustrated faintly by a gas-engine or jerky motor of any kind, and the regularity and dependableness of a storage cistern may very well make it desirable to put up with some waste provided it be not excessive. Mechanical devices for approximating to regularity, such as the use of slack driving belts, undoubtedly give rise to a waste of power, and so does any form of regulator. But in the utilisation of artificial forms of power like this, questions of economy become almost pre-eminent; and wastefulness is here a most serious objection, and, it may be, prohibitive defect. At the same time, if the engine is liable to stop, or if it is not always working, some mode of storing energy may be absolutely necessary, whether wasteful or not.

(3) Another case, and to some extent the converse of the last, is when the available source is weak, though continuous, while the power is only needed for a short time, but during that time is required to be great. This is exemplified in the operation of pile-driving, where energy is stored in the slowly-raised weight to be suddenly expended on the head of the pile, also in the operation of drawing a bow; or again when a small waterfall or steam-engine, running continuously, is to be utilised for lighting during five or six hours each day: the obviously right plan in such circumstances as these is to store the energy during the hours it is not wanted, and thus virtually to double or treble the power of the source while it is actually in use. Unless, however, the loss occasioned by storage were reasonably small, there would be but small gain in attempting the process in this third case.

It is plainly advantageous to devise a method of storing that shall give out the greater part of what is put in; but we see by these examples that a reasonable loss may be more than compensated by convenience, regularity, availability, and dependableness. Again, when energy has to be transmitted over great distances, it is in practice difficult or impossible to make the expenditure of energy at one end depend upon and be regulated by its consumption at the other; and so, without some system of storage, great waste will ensue during intervals of small consumption. Looking to the immense development which the transmission of energy may be expected to undergo in the course of the next few decades, a convenient and manageable method of receiving large quantities of transmitted energy, and of holding it in readiness until wanted, must be of prime importance.

It was in view of such applications as these that the invention of the storage battery by Faure was hailed with enthusiasm by the highest scientific authority in Great Britain; while the public, jumping to the conclusion that a thing for which so many uses could be instantly found must needs be a profitable investment, hastened to provide money, not for commencing careful experiments and perfecting the arrangement, which would have been wise, but for manufacturing tons of apparatus in its first crude, immature, and untried form. Some day it may perhaps be recognised that because it can be shown that a thing will be extremely useful when perfect it does not follow that it has already attained that perfection, that indeed probabilities based on historical developments are enormously against such abnormal and instantaneous maturity, and that the careful nursing and rearing necessary to healthy maturity are better given in the seclusion of laboratory and study than in the excited and heated atmosphere of the Stock Exchange. It is doubtless recognised already that all preliminary operations are better conducted on a scale smaller than the wholesale manufacturing one. In developing a new industry there are scientific difficulties to be overcome, and there are manufacturing difficulties. By scientific difficulties we mean such as the determination of weak points, the best ways of strengthening them, and generally the discovery of theoretically the best modes of effecting the object in view: manufacturing difficulties begin with questions of expediency and economy—how most cheaply and satisfactorily to carry out the indications of theory, to obtain this or that material—and include the organisation of a system of manufacture, of division of labour, of machine tools, which shall enable the work to be done with economy, security, and despatch. Over-haste in the preliminary stages causes both these sets of difficulties to be tackled together, and so throws a grievous burden on both adviser and manager. All these untoward conditions have storage batteries experienced; and to say they have not fulfilled the hopes of their early promoters is no more than to say that those hopes were untimely and unreasonable. The period of maturity has been undoubtedly delayed by injudicious treatment, but its ultimate attainment seems to us inevitable; and it is at present a matter of opinion how nearly it has already been reached: certainly great steps towards it have been made. Let us inquire what some of the difficulties encountered have been, and it will be seen that, formidable as some of them are, they belong essentially to an infantile stage, and are not suggestive of constitutional debility.

The first form of manufacture consisted in rolling up sheets of lead and composition, with trousering to keep them separate. The difficulties found were that the coatings would not adhere, but became detached in large flakes; that the trousering got corroded through and permitted short circuiting; and that free circulation of fluid being impossible, the acid became exhausted in some places and concentrated at others, and thus every sort of irregularity began. Now regularity or uniformity is of the most vital and fundamental importance in any form of battery. If any part of a plate is inactive, that part is better away; if any plate in a cell is inactive, it is better away; and if any cells of a battery are inactive, they are infinitely better away. The rolling or coiling up of the sheets being found awkward in practice and liable to detach the coatings, flat plates came to be used, then perforated plates, and then cast grids; these last having such large hole space that they held enough composition, and held it securely enough, to enable the trousering or intermediate porous material to be dispensed with. This was an evident step in advance: free circulation of the liquid became possible, and could be assisted by stirring; there was nothing to corrode except the plates themselves, and the composition, being in the cells or holes of the grid, might be reasonably expected to adhere. So far expectation was not altogether belied. The adhesion was not perfect, it was true, and pieces of composition sometimes fell out of the holes, especially if too powerful currents were passed through the cell, but still it was much better than it had been; and if the plates were well filled, properly formed, and fairly treated, the composition adhered extremely well and securely. The circulation of the liquid was not automatically perfect either, but mechanical agitation could be readily applied; without it the acid near the bottom of the cells tended to become more concentrated than that near the top, not by reason of gravitation

undoing diffusion, which is impossible, but because during each charging fresh acid is formed, and in great part falls to the bottom in visible streams. Another great advantage was that some amount of inspection of the plates became possible, and experience as to the actual behaviour and appearance of the plates, began to be accumulated. And painfully varied that experience was. Every variety of extraordinary behaviour which could be suggested as probable, and a good many which no one could possibly have imagined beforehand, made their appearance. The hundreds of tons of batteries made at this period doubtless enabled these unpleasant experiences to be more rapidly acquired than would have been done on a small scale, but it was a costly series of experiments. However, the experiments were made, the public involuntarily assisted in the acquisition of experience, and, caring less for knowledge than for marketable commodities, they expressed dissatisfaction at the result. Many of these incipient difficulties are now overcome by the manufacturers, but the great dislike of the public to involuntary experiments, and the shock which their confidence underwent on being unexpectedly called upon to participate in research, have not yet altogether abated.

The main difficulty now experienced was how to keep the plates from touching. They might be put in wooden frames, or elastic bands might be stretched round each of them, and if they would only keep flat it was impossible they should touch unless the composition should drop out of the holes. Sometimes the composition did drop out of a hole, and bridge across the interval between two plates, but the more common and more fatal experience was that the plates would not keep straight. In a few months the positives were found to swell, and as they swelled to buckle—to buckle and twist into every variety of form, so that elastic bands, wooden frames, and every other contrivance failed altogether to prevent short-circuiting. The cause of the buckling is of course irregular and one-sided swelling, and the cause of the swelling is apparently the gradual peroxidation and sulphating of the material of the bars of the lead grid, which occupy less room as metallic lead than as oxide or salt. As the bars swell, they press on the inclosed composition, occasionally driving it out, but more frequently, and with properly made and treated plates universally, distending themselves and stretching the whole medial portion of the plate. The edge or frame of the grid is stronger than the middle bars, and is not so easily stretched; in a good and uniformly worked plate it does stretch, and an old positive plate is some quarter of an inch bigger every way than a new one, but if one face of the plate is a trifle more active than the other, it is very plain that the most active side will tend to become convex; and buckling once begun very easily goes on. To cure it two opposite plans have been tried: one is to leave the plates as free and unconstrained as possible, hanging free it may be from two points, thin, and with crinkled or crimped margins to allow for expansion; the other is to make them thick and strong, with plentiful ribs for stiffness, and besides to clamp them up one to another as tightly as may be, and thus in mechanical ways to resist buckling and distortion. I do not know that any one could say for certain beforehand which of these two plans would be likely to answer best, but practice is beginning to reply in favour of the latter, and well braced plates of fair thickness show no unmanageable tendency to buckle. It must be remembered that no material can buckle with a force greater than that necessary to restore it to flatness, and this force in the case of lead is very moderate. Hence it may be fairly hoped to overcome and restrain all exuberances by suitable clamps and guides arranged so as to permit flat and even growth, but to check all lateral warpings and excrescences.

Uniformity of action is still essential, especially if all the plates in a cell are clamped together. Plates mechanically treated alike ought to be electrically so treated also, and it is impossible to keep a set of plates working satisfactorily together unless the contact of each is thoroughly and equally good, so that each may receive its fair share of current. Defects of contact have been a fruitful source of breakdown and irregularity. Clamps and screws of every variety have been tried, but the insidious corroding action of nascent oxygen exerted through the film of acid which by spray and creeping forms and concentrates on the lugs—this corroding action crawls between the clamped surfaces, gradually destroys all perfect contact, and sometimes produces almost complete insulation. Contacts on the negative plates give but little trouble; contacts on the positives have taxed a great amount of patience. Lead contacts "burned," *i.e.* melted, not soldered on, are evidently less liable to corrosion than brass or copper fittings, or than any form of clamp, but they are apt to be somewhat clumsy if of sufficient conductivity, and moreover they are awkward to undo again, and somewhat troublesome to do. However they have proved themselves so decidedly the best that now no other contacts will be used, and their re-introduction has been followed by a marked improvement in the behaviour of the cells. So long as contact with one plate was better than with another, a thing quite possible to happen without any difference being perceptible to the eye, so long was it possible for one or two plates to remain almost wholly inactive while another one or two received far more than their share of current, and became distended, warped, overcharged, and ultimately crumbled away. If one or two plates in a cell are black, and giving off torrents of gas, while the rest are brown and idle-looking, it is pretty fair evidence of irregular and insufficient contact, or else of some great discrepancy in the age or make of the plates. This point also is one that was not attended to in the early stages of manufacture; plates were made for stock, and cells were made up with plates of all ages selected at random from the store. Directly uniformity is perceived to be essential, this is recognised as obviously bad. Plates intended to work together should be of the same age and make, and inasmuch as keeping does not improve them, the best plan is not to make for stock, but to keep material ready, and then quickly make up as wanted. Plates in work deteriorate slowly, but they are wearing out in the fulfilment of their proper function; plates in idleness deteriorate as quickly, and they are rusting out in fulfilment of no function at all. Worn-out plates, however, are by no means valueless. Lead material has a well recognised price, and if attention were given to the subject, it is probable that decrepit and useless plates might be made to yield a very large percentage, if not the whole, of their original lead. For it must be remembered that plates deteriorate not by waste but by accretion: an old plate contains as much lead as a new one, but it contains it with the addition of oxygen and sulphion; no longer a tenacious coherent frame, but a crumbling mass of incoherent powder.

The age of plates is a point of vital interest, though but little is known as to the possibilities in this direction at present. A year may be regarded as a fair average age at the present time; but this is a low rather than a high estimate. Thick plates are found to last far longer than thin, which is only natural when it is remembered that the wearing out is due to corrosion, that corrosion proceeds mainly from the surface inwards, and that the internal portions of a thick plate are to a great extent protected by the mass of superincumbent material. If it can be shown, as we understand it can, (1) that the cost of materials is far more than the cost of manufacture; (2) that the worn-out material has a market value not incomparably less than the original; and (3) that the frequency with which plates have to be renewed is not such as to cause much inconvenience; then we hold that the first stage of the durability difficulty has been over-

come. Much more may be hoped for in this direction as experience increases, and it is not extravagant to hope that a well-ribbed, properly-clamped, and fairly-treated thick plate may last as long as five years before it becomes disintegrated.

It is evident, however, that in a region where pure experiment is pre-eminent, and where the units of time are months and years, instead of hours and days, the accumulation of experience is a slow and tedious process. It is no use making statements involving periods of five years when no one has had the present improved form in use for so much as six months. Nevertheless it is possible to see that the present cells are better than their predecessors; and as their predecessors have lasted in good condition for a year and more it is not presumptuous to indulge in well-founded hopes. Many of the difficulties connected with the early forms of battery were aggravated by Utopian notions concerning internal resistance and compactness. The internal resistance of a cell was so beautifully small, that the manufacturers were tempted to diminish it still further by putting the plates far too close together. An eighth or tenth of an inch interval is well enough if the plates had been hard rigid slabs of perfect flatness; but it was madness to pack flexible lead plates full of composition certain to swell and liable to drop out so near together as this. Security and dependableness were sacrificed to a natural desire for sudden and Utopian perfection. We may hope that these lessons have been profited by, and that the manufacturers perceive that confidence and security are the first conditions of success, and that minutiæ as to the number of noughts before the significant figures in the specification of resistance begin, though those also are of importance in their turn, are yet of quite secondary consideration. Moreover, this packing of the plates so closely did not really do much to secure the result desired; the greater part of the resistance of half run-down cells is not in the liquid between the plates, but in the surface or scum separating each plate, and especially each negative plate, from the liquid, and hence putting the plates a safe distance, say a quarter or one-third of an inch, apart exerts an effect on the total resistance which is certainly far more than compensated by the ready opportunity thus afforded for access by both sight and touch. The old opaque boxes chock full of plates, with slight india-rubber bands between them, were started and left to Providence. No one could see what went on, nor could one readily get at anything to rectify what was wrong. In the present glass boxes properly arranged on accessible shelves with only plugs or studs between the plates, clear vision through the cell in any direction is easy, and accidental obstruction not only very seldom occurs but if it does it can without difficulty be seen and removed. But it must be granted that these boxes are less compact than their predecessors, and for some purposes, such as locomotion, compactness is of the first importance. Most true, for some purposes. It is not to be supposed that one type of cell will answer every possible demand. A dynamo to be highly efficient must have a large and massive field magnet, but in some places bulk and weight are fatal objections, and in these places smaller and more compact dynamos may be more suitable: something, however, must be given up to secure the required lightness and compactness, some sort of compromise must be effected. Just so with cells: we can point out what is theoretically the best form, and this form may, for large stationary electric light or power installation, be actually the most suitable; but we may also see that for boats, for tramcars, and for fish torpedoes, some very different and far more compact form may be quite essential.

Efficiency, Durability, Economy, Compactness: it may not be possible to attain all these at once—if it were, there would be small room for discussion—but sometimes one and sometimes another will be the pressing necessity, and manufacturers of storage batteries, like manufacturers of dynamos, must be prepared with forms suited to various needs.

We have spoken mainly of difficulties connected with the positive plates, and have said nothing concerning the negatives. It is not that these are not susceptible of improvement, but their faults have been of a less imperious and obtrusive nature. They are not perfect, but they do fairly well, and there has been little need to worry much about them, until the extraordinary behaviour of positives had been taken in hand and checked. The time is coming to attend to these also. They fail not from exuberance, but from inertness. As they grow old, they do not swell, and warp, and burst, and crumble, like the positives, but they grow quietly hoary, and serenely decay. The composition in a worn-out negative consists of white sulphate through and through, but the frame remains intact, and it consequently never falls to pieces, nor does it swell. Impurities in the acid used tell upon a negative plate—nitric acid is fatal. Acid much too weak or very much too strong is also deleterious, and idleness is bad. The difficulties connected with negatives mostly depend on their aggravating property of always requiring a quite opposite treatment to positives. The less a positive is formed and overcharged the better. A negative delights in complete formation and frequent overcharge. In recognition of this it is now customary to form them separately, and to give the negative a thorough dose of hydrogen without commencing the corrosion of the positive by an overdose of oxygen. When the discharge from a cell begins to flag, it is the resisting scum of sulphate that has formed over the negative plate which is responsible for the flagging. The true E.M.F. of a cell is wonderfully constant throughout the whole discharge; but the internal resistance is all the time increasing, at first very slowly, ultimately, towards the end, with a rush. One such run-down cell in the midst of a lot of others therefore obstructs the current terribly. If only a series of cells could with certainty be made to work together uniformly, if a series could behave as well as some of the cells in it, no one would have cause to complain.

Through the whole history of the manufacture, from the very beginning, a few cells here and there have always exhibited astonishing efficiency;—the aim of manufacturers may be said to be to bring all cells up to the level of a few. Much progress in this direction has been made, and it may be very fairly expected that, as uniformity is gradually attained, a series of cells subjected to the same treatment may behave in the same manner. Whenever this is certainly accomplished, there will have been reached a high stage of efficiency, beyond which further progress need be only in the improvement of comparably insignificant minutiæ.

The subject of the electrical storage of energy is really one of national importance;—it is comparatively a small matter whether this or that form of storage, or this or that company of manufacturers, succeeds in bringing out the permanent form. It sometimes unfortunately happens that enterprising pioneers only clear the way, and retire just in time for other men to come in and reap the fruits of their labours. So much capital and so much labour have been already expended in the effort to bring storage batteries to perfection, so great progress has been made, and so apparently small are the steps which yet remain to be accomplished, that we may surely fairly hope that some of the original believers in their great, and as it seems to us inevitable, future may yet live to see their faith justified and their patience rewarded, and may even taste some of that so-called "substantial" reward without the hope of which great commercial enterprises would never be undertaken, and modern civilisation would have scarcely yet begun.

O. J. L.

METEOROLOGY OF THE LOWER CONGO[1]

IN this work Dr. Danckelman has made a valuable contribution to the meteorology of Africa. The observations, which are printed *in extenso*, were made at Vivi, lat. 5° 35′ S., long. 13° 52′ E., at a height of 374 feet, from May 1882 to August 1883. The hours of observation were 7 a.m., 2 p.m., and 9 p.m., and to these were added for the six months ending May 1883 observations at 6 a.m. and 8 a.m., which thus furnish important data regarding the march of diurnal phenomena for the first three hours after sunrise. The full details which are given of the instruments employed, their exposure, and the methods of observing are particularly satisfactory. While the instrumental observations are very complete, no less care has been taken to make the non-instrumental observations of weather equally complete, and these have been planned and carried out to aid in discussions affecting both local and general meteorology.

In resuming and discussing these sixteen months' observations, Dr. Danckelman has conjoined with the results obtained for Vivi the results of observations made at St. Thomas, Gaboon, Chinchoxo, Loanda, and Melange, these places roughly representing the west of Africa from near the equator to about lat. 10° S. At all these places the annual minimum pressure occurs in February or March and the maximum in July, with a small secondary maximum in January. At Vivi atmospheric pressure at 32° and sea-level is 29·932 inches in February, 30·117 inches in July, and 29·997 inches for the year.

At Vivi the mean annual temperature is 76°·4, the lowest monthly mean being 70°·5 in August, and the highest 79°·5 in February. The highest observed temperature was 97°·2 on November 5, 1882, and the lowest 53°·8 on July 29 of the same year. A noteworthy feature of the climate of Vivi is the relatively low temperature from June to September; during the other eight months the means vary only from 77°·4 to 79°·5. This feature is common to the whole of this region of West Africa; and it corresponds to the dry season of the year, which, as regards the Lower Congo, is characterised by Dr. Danckelman as undoubtedly the most agreeable and the finest, as well as the healthiest, season of the year. On the other hand, on the elevated plateaux of the interior, the heat is very great during the day, and many maladies prevail among the natives, numbers of the ill-clad blacks succumbing to the diseases caused by exposure to the low temperature of the nights. The temperature of the Congo was observed at intervals during the year, the observations being made at a part of the river where the current was rapid. The results give a mean annual temperature of 81°·8, being thus 5°·4 higher than that of the air.

Of the winds observed at Vivi the percentages are south-west, 39; west, 15; west-south-west, 9; north, 8; and calms, 18; winds from any other direction being of rare occurrence. Thus of the 82 per cent. of wind-directions observed, 63 per cent were from the south-west quadrant. During the whole year south-west winds predominate in the afternoon, but during the dry season the wind frequently veers to west towards evening, so that at 9 p.m. west and west-south-west winds are more frequent than south-west, whilst south and south-south-west winds very rarely occur. This striking predominance of south-westerly winds has important bearings on the climatology of the whole of the Lower Congo as respects humidity, cloud, and rainfall. A striking peculiarity of the climate are the strong winds which often set in late in the afternoon and evening, and which are carefully recorded in the journal of the observations. The following are the number of times such winds have occurred each hour from 3 p.m. to 11 p.m.,—6, 11, 24, 28, 30, 32, 22, and 4, the hours of greatest frequency thus being from 5 p.m. to 10 p.m. During the other hours of the day they seldom occur. The degree to which this prevails is seen from the fact that the mean force of the wind is greater at 9 p.m. than at 2 p.m., the latter hour being the time about which the wind generally attains its maximum diurnal velocity over the land.

Thunderstorms are of frequent occurrence from November to May, but none were recorded from June to October. As regards their distribution during the day, scarcely any occurred from 11 p.m. to noon, the period of maximum frequency being from 1 p.m. to 8 p.m.; but particularly from 4 p.m. to 6 p.m., 29 per cent. of the whole having occurred during these two hours. During the rainy season heat lightning is of frequent occurrence in the south, east, and north horizon, but rarely in the west. When the wind shifts from the ordinary south-west direction into east, the change is almost invariably followed by a thunderstorm, or by thundery-looking clouds, which indicate a thunderstorm not far off. Thunderstorms most frequently advance from the east. During the sixteen months the number of storms which advanced from an easterly direction was fifty-three, whereas only fourteen came from a westerly direction. The severest thunderstorms come from the north-east. They are intimately connected with the rainfall, which being wholly dependent on the thunderstorm, the diurnal periods of the two phenomena are the same. The rainiest months at Vivi were November, 11·34 inches; December, 8·94 inches; April, 9·10 inches; and March, 5·67 inches. The annual amount was 42·56 inches. No rain fell from June to September, and the fall in October was very small. During the dry season, however, when no rain falls, the hygrometer not unfrequently indicates an atmosphere highly charged with vapour, and occasionally a light drizzle sets in which the Portuguese call "Cacimbo," but the amount falling is too small to be measurable. These results show, in an unmistakable manner, the powerful and beneficial influence of the prevailing south-westerly winds from the Atlantic on the climate of this extensive region in the continent of Africa.

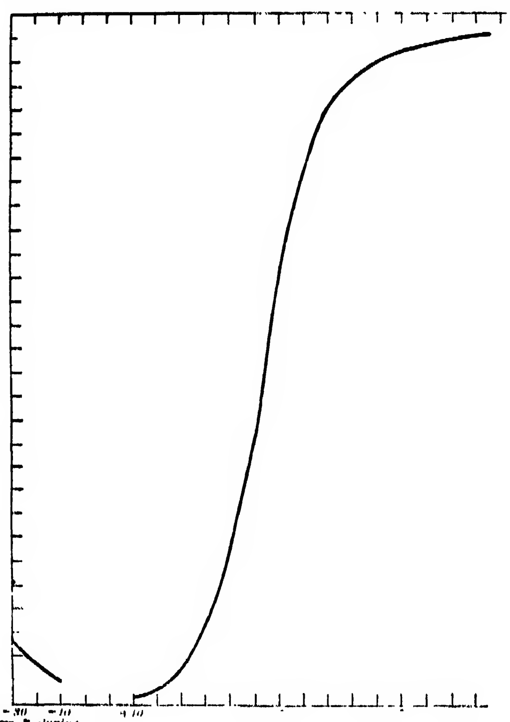
THE RECENT ECLIPSE OF THE MOON

WE have received the following communications with reference to the recent lunar eclipse:—

THE total eclipse of the moon on Saturday, October 4 was of particular importance as it was—since the one in 1877, which was practically lost through bad weather—the first opportunity of measuring the changes which the heat radiated by the moon undergoes with the proceeding eclipse. And indeed on Saturday evening at six o'clock it appeared highly probable that the fate of this eclipse would be the same as that of its predecessor, the sky being thickly covered with misty clouds, with hardly any motion whatever. Suddenly, however, as if by magic thirty-two minutes before the beginning of the total phase they all disappeared, and left a most perfect and exceptional clearness behind them, which not only lasted during the remainder of the eclipse, but also through the two following days and nights. Thus I was enabled to carry out the greater part of my programme in every detail. The apparatus used was the same which the Earl of Rosse described in his communications to the Royal Society in 1869, 1870, and 1873; it condenses by means of two small concave mirrors alternately on two thermopiles the rays of the moon collected by the 3-foot telescope, and the currents thus created are measured by the aid of a galvanometer with mirror and scale. The time of exposure was 1 min. sid. time for each pile, and the observations were throughout the eclipse carried on with only two interruptions of eight and nine minutes, the former caused by my examining the condensing mirrors for dew, th

latter by the re-winding of the driving-clock of the telescope. Thus I took altogether 211 readings of the galvanometer, which were taken together in groups of ten for the formation of reliable mean values. It is these means—without the application of the still necessary reductions—which form the ordinates of the preliminary curve inclosed, the abscissæ of which are the times before the beginning and after the end of the total phase. It will be seen that no observations were made during the total phase, as I could not make certain that the moon's image was actually on the condensing mirrors; besides the readings of the galvanometer on near approach to the total phase became so unsteady and irregular that it was plain that the effect, if any, fell below the sensitive-



Curve showing the change of the lunar radiant heat as measured by thermopiles and galvanometer during the total eclipse of the moon on October 4, 1884, at Birr Castle Observatory, by Otto Boeddicker.

ness of the instrument and the unavoidable errors of observation. This is much to be regretted, as the few observations obtained before the total phase began show plainly that the minimum of the radiated heat takes place later than that of the moon's light. Indeed, so slowly did the readings of the galvanometer increase again that about twenty minutes after the total phase was over the almost entire absence of any effect led me to think that the small condensing mirrors must be covered with dew, an apprehension which was happily not verified. I should add that the galvanometer readings here given are not comparable with those published in 1873.

OTTO BOEDDICKER

The Earl of Rosse's Observatory, Birr Castle, Parsonstown

THIS eclipse was seen from here (height above sea 530 feet) to great advantage in a cloudless sky, with the stars very brilliant and the air calm.

For some minutes before the actual contact a faint smoky look was visible, and this had the effect of flattening the edge of the moon on the side towards which the shadow was approaching. At 8h. 16m. there was a slight but very perceptible shadow, about a fourth of the moon's diameter in advance of the dark shadow, and in four minutes later the eclipse just entered the moon. At 8h. 44m. the margin of the dark shadow, which had had all along an edge of a woolly and irregular appearance, had now decided streaks in advance of it. The edge of the moon on the opposite side from the base to within 30° of the apex was marked by a rim of intense bright *blue*. Ten minutes later the blue margin was less brilliant and narrower, and the woolly appearance before mentioned was more decided, but less streaky. At 8h. 58m. the *blue* had contracted in length both at the base and apex, and gradually assumed a greenish shade. The cusps of the moon were elongated and more drop-like than continuous. At 9h. 18m. the shadow had almost covered the moon, which showed a faint glow beneath, though the circular appearance was not visible to the naked eye. A minute later, as the last point of light disappeared, a dense blackness of irregular form appeared on the opposite portion of the moon, extending over nearly a third of the surface. At 9h. 39m. the moon was scarcely perceptible to the naked eye. Through the telescope a faint luminosity at the apex could be discerned. At 9h. 47m. to the naked eye the moon seemed like a blurred star, very indistinct and considerably reduced in apparent size, and of no definite form. At 10h. 2m. the faint luminosity at the apex had almost gone, and the outline of the moon was more apparent through the telescope. The blurred, star-like appearance to the naked eye was still unchanged. At 10h. 9m. there was a thin luminosity on both horizontal sides of the moon. The apex of the moon was very indistinct. At 10h. 20m. a broader belt of light appeared on the northern side, but that on the opposite side was indistinct. There was still the same indistinctness to the naked eye, though every now and then a faint crescent-like appearance could be seen. At 10h. 38m. a somewhat broader crescent. At 10h. 43m. a bright light like that of the moon was visible to the naked eye at the apex, and four minutes later the moon reappeared. At 10h. 57m. the tip of a mountain was lit up near the moon's apex. At 11 p.m. the upper cusp extended further than the lower one. At 11h. 15m. a slight haze formed a burr about the moon, which was somewhat kidney-shaped. At 11h. 22m. the burr still visible, but much rounder in form. The eclipse ended at 11h. 45m.

Having previously observed a number of lunar eclipses, I was specially struck with that of to-night; the density and blackness of the shadow was far greater than any previous one that I had seen, especially throughout the period of totality. In all previous eclipses I have been able to trace the outline; in the present case this was quite impossible. Usually the outline is more or less plainly seen, and not unfrequently there is a strong reddish light. The last total eclipse of the moon was seen from this place, and it had a copper-coloured appearance, and there was no difficulty in tracing the outline. In the present eclipse the moon's outline was invisible for some time to the unaided eye, and the apparent size so much diminished that it had more the appearance of a large star whose light was just able to pierce through a dense haze. Some of the valleys of the moon were left for a time in great darkness after the light had travelled beyond them. I may mention that all the above appearances were also seen by Major A. E. L. Lowe and Mr. H. L. P. Lowe, who were using other telescopes.

E. J. LOWE

Shirenewton Hall, near Chepstow, October 4

IT is to be hoped that the unusual phenomena attending the late eclipse of the moon may lead to a discussion which will throw some light upon the great differences observed on different occasions in the visibility of the eclipsed moon—differences which have not hitherto, so far as I know, been adequately explained.

In the late eclipse, as viewed from this station (where the sky was not only perfectly cloudless, but free from the least suspicion of haze), the obscuration of the moon was carried to a degree far beyond anything witnessed in the eclipses of recent times. For some time before and after the middle of the eclipse (that is, about 10 p.m.) the only trace of our satellite that remained in the sky was a faint dingy-brown nebulous spot, to which it was impossible to assign any definite form or dimensions, but which certainly did not approach the moon in point of apparent size. So inconspicuous was it that it was quite invisible through the window of a room in which lights were burning: and in the open air, if one had not known exactly where to look for it, one might have searched for some little time without discovering it. I speak of course of the naked-eye appearances. With an opera-glass the nebulous spot was resolved into a well-defined disk of the proper dimensions, but still very faint and dingy, the hue being a kind of reddish-brown. It was further remarked that the illumination was uniformly distributed over the disk, at least so far as this, that there was no preponderance of light in the direction of any one part of the moon's edge. This is what should naturally have followed from the central character of the eclipse, but it seems desirable to note the circumstance with reference to a theory presently to be mentioned.

The most obvious explanation of the unusual obscurity of the moon would be its unusually deep immersion in the earth's shadow, but this view seems to be clearly disproved by a comparison with the phenomena observed in a former eclipse. Referring to a note which I made at the time of the eclipse of August 23, 1877, I find the following remark :—"The moon, even in the middle of the total phase, was a conspicuous object in the sky, and the ruddy colour was well marked. In the very middle of the eclipse the degree of illumination was as nearly as possible equal all round the edge of the moon, the central parts being darker than those near the edge." Now the duration of totality in that eclipse was 1h. 44m. In the late eclipse it was 1h. 32m. The immersion of the moon in the earth's shadow must therefore, I presume, have been at least as deep on the former occasion as on the recent one. It may be mentioned as an additional argument against this explanation that in the late eclipse the visibility of the eclipsed portion was observed to be much less than usual even before the eclipse was complete. In fact it was not until within a few minutes of the total phase that the eclipsed portion could be certainly distinguished with the naked eye.

Another obvious suggestion in the way of explanation has reference to variations in the condition of that portion of the earth's atmosphere through which the sun's rays would pass to reach the moon. This explanation is not without interest in connection with the remarkable sunset effects of last winter, and, in a less degree, of the present autumn. But there are serious difficulties in the way of accepting it, for, in order to account for the observed phenomena, it would be necessary to suppose that an entire ring of the earth's atmosphere was uniformly affected. A want of uniformity in this respect would not cause merely an uneven illumination of the moon's disk, which some observers seem to have noted, and which may very well be set down to the actual differences on the surface of the moon ; the effect would be specially marked upon some part of the moon's edge, and would be similar to what is observed soon after totality has commenced and shortly before it ends. Nothing approaching to this appearance was to be seen in the late eclipse at the time when the obscuration was greatest.

Is it possible that the surface of the moon may be in some small degree self-luminous, and that a variation (from unknown causes) in the degree of this self-luminosity may account for the difference observed in the visibility of the moon in two eclipses, in both of which the solar light was equally at its minimum?

Clifton, October 7 GEORGE F. BURDER

ON the occasion of the total eclipse of the moon on Saturday, October 4, the Director of the Pulkowa Observatory, near St. Petersburg, issued a circular to a number of other observatories suggesting the use of the opportunity to fix the exact diameter of the moon, the mean value of the true diameter not being known to a second. Even as regards a probably existing depression of the surface of the moon, we know only that it cannot be very great. The circular also requested observers to watch attentively all stars, even those of the tenth magnitude, eclipsed by the moon, and their egress on the other side, which is only possible during a total eclipse. In order to make these observations exact, Prof. Döllen, of the Pulkowa Observatory, calculated the number of such stars covered by the moon on that date, which he finds were 116, most of which are of the ninth and tenth magnitude and only one of the sixth. He has, moreover, for the use of observers, calculated the exact position of these during the eclipse for no less than sixty observatories from Pulkowa to the Cape, which is expected to give the desired result.

NOTES

OUR readers will hear with sincere regret that Prof. Huxley, under the orders of his medical advisers, left England yesterday for some months of absolute rest. When it is remembered how many functions Prof. Huxley has to fulfil, we need hardly say that the cause of his enforced retirement for a time is overwork. His presence in England will certainly be missed during the coming winter, and he may feel assured that he carries with him the sympathies of many friends, known and unknown. Prof. Huxley goes in the first instance to Venice.

WE heartily support the suggestion which has been made in the *Gardeners' Chronicle* that it would be most appropriate that some memorial of the late Mr. Bentham should, subject to the consent of the authorities, be placed in the Royal Herbarium at Kew, to which he was such a benefactor, and in connection with which his life-work was for very many years carried on. Official etiquette would probably preclude any steps being taken by the authorities at Kew in the matter; and, indeed, it is a subject that would more gracefully and appropriately be dealt with by outsiders.

SIR WILLIAM HARCOURT is always happy when he touches on science, either to point a political shaft, or, as on Tuesday at Derby, when descanting directly on its progress and bearings. He showed himself well versed—as one bearing the honoured name of Harcourt ought to be—in the history of scientific progress, and in the high importance of science apart from its utilitarian uses. Scientific study, in his conception, is above all others "the most useful and the most ennobling." "Depend upon it," he concluded, "if I may turn for a moment to the utilitarian view, these are not days in which we, as a people, can afford to be idle or to be ignorant. There is an immense competition going on in the world in all departments of trade. Remember you have the competition of countries where education of this character is of a more complete character, far more complete than anything we have in this country. If you go into Germany you will find in every small town that there are institutions where the severest education is given in all departments of technical knowledge. The old days when people could afford to go on in an easy, happy-go-lucky sort of manner are gone by. You may depend upon it, in the race which we have to run in the world, a training of the severest description is requisite, so that we may hold our own." We trust Sir William will bear his admirable Derby

utterances in mind when as a legislator he has to consider the relation of science and of scientific workers to the Government and the country.

PROF. HUGO GYLDÉN, Director of the Observatory at Stockholm, and well known for his studies during recent years of the eight great planets, has been offered and has accepted the Professorship of Astronomy at the Göttingen University.

HIS MAJESTY the King of Italy has conferred the decoration of Knight of the Crown of Italy upon Deputy-Surgeon-General Francis Day, formerly Inspector-General of Fisheries in India, and lately Commissioner of the Indian Section in the great International Fisheries Exhibition.

DR. SOPHUS TROMHOLT having returned to Bergen after a lengthened sojourn in Iceland, whence we have from time to time received accounts of his researches, intends for the next few years to devote his time to the production of a great catalogue of all the auroræ seen in Northern Europe from the earliest times. The Norwegian Government have granted a not inconsiderable sum towards this gigantic undertaking. As this labour and the imminent production of his new work, "Under the Rays of the Aurora Borealis," will occupy all his time for some while, the distinguished *savant* announces his inability to issue for the coming winter such sheets for the recording of auroræ as he has for some years been in the habit of distributing over all parts of Northern Europe. He trusts, however, that observers may continue to note the phenomena as heretofore on the lines laid down by him, and forward the same to him with as little delay as possible. His address is Bergen.

CHANDA SINGH, a blind student of St. Stephen's College, Delhi, is, according to the account given in *Allen's Indian Mail*, a prodigy. He cannot read or write, but possesses such a strong memory as to be able to repeat all his text-books, English, Persian, or Urdu, by rote, and to work out sums in arithmetic with remarkable rapidity. The unusual intensity of his mental powers is shown by his ability to multiply any number of figures by another equally large. At the last University examination he was examined *vivâ voce* by order of the Director of Public Instruction of the Punjaub, and he stood twenty-seventh in the list of successful candidates. On the recommendation of the same official, the judges of the local court have allowed him to appear at its law examination. Memory, as is well known, is wonderfully developed in Orientals, owing to the system of education which has obtained amongst them; but cases like Chanda Singh must be very rare even in the East.

DURING the last week of September the Thüringo-Saxon Verein für Erdkunde held its annual meeting at Kösen under the presidency of Herr Dunker (Halle). Amongst a number of interesting papers read we note the following:—On Baku and its naphtha and petroleum wells, by Herr Eberius (Döllnitz); on the scientific and economical importance of Cameroon, by Prof. Kirchhoff; on the limits between the High and Low German on the eastern side of the Elbe, by Dr. Haushalter (Rudolstadt); on the salt and fresh-water lakes between Halle and Eisleben, by Prof. Kirchhoff; on ancient places of worship in Northern Thüringia, by Dr. Rackwitz (Nordhausen).

THE thirty-second annual meeting of the German Geological Society took place at Hanover in the last week of September under the presidency of Herr von der Decken. Among the papers read we note the following:—On the limits of the Dyas formation, by Prof. Geinitz (Dresden); on the geology of North-Western America, by Prof. vom Rath (Bonn); on the Brachiosaurus occurring in the Hessian limestone, by Prof. Credner Leipzig); on the geology of the Harz Mountains, by Herr Langsdorff (Klausthal); on the occurrence of dolerite in the Vogelsberg, by Prof. Streng (Giessen); on Tasmanian tin ores, by Herr Gordaek (Klausthal); on new Devonian Bryozoa, by Dr. Bornemann (Eisenach). The next place of meeting will be Darmstadt.

WRITING on a subject of some interest at the present time, viz. the orthography of the names of the better known Chinese places, a correspondent of the *Tablettes des deux Charentes* says that *Tonquin* is more correct than *Tonkin* (and we presume also than *Tongking*, *Tonking*, &c.), for this is how the name is pronounced. He thinks that French pronunciation generally approaches that of the Chinese more than the English. Thus the Chinese have the nasal sound of *n* and a sound of *u* which we in England do not possess. We cannot always reproduce these Chinese sounds, while the French can do so easily. To represent the nasal sound the English add a *g* to the *n*, but they do not always pronounce it. The French borrow the English orthography, but they pronounce the *g* which the former have added, and thus completely disfigure the names. Thus (the correspondent goes on) the French pronounce *Shangai* instead of *Shanhaï*, and *Hongue-Kongue* in place of *Hon-Kon*. The most curious instance is that of *Canton*. The English call the province *Kwang-toung*; all the French journals follow this orthography, and yet it is Canton pure and simple. If the *k* is to be employed at all it should be written *Ton-Kien*, for we write *Fo-Kien* as the name of the province in which Foochow is situated, and the *Kien* is the same in each instance. The truth appears to be that all Far Eastern names have been transliterated haphazard, and almost in every case by people who knew nothing of the native languages. The older orthographies, such as Canton, Whampoa, &c., we owe to masters of ships, supercargoes, and the like, who visited the place in the last or beginning of the present century. In some cases they are not good attempts at reproduction, but little practical inconvenience has ever been found in adhering to them. According to the writer whom we have quoted the French are in a worse plight than ourselves; our orthography was at least an honest attempt to reproduce the names as they sounded to Englishmen. The French adopt this orthography, and then give the letters their French pronunciation; in other words the transmutation is (1) Chinese as it sounded to an Englishman; (2) that Englishman's Chinese as it sounded to a Frenchman! Little wonder then that there are hopelessly irreconcilable methods of spelling Chinese names of places.

THE Japanese Commissioner to the Health Exhibition writes that the omission of the names of the foreign authors of certain scientific works in the Japanese Section was quite unintentional. He adds that three of these works are by Japanese assistant professors. The omission, on which we commented last week in noticing the Catalogue, coupled with the statement that the English volumes were translations, was certainly calculated to leave an erroneous impression as to the authorship of the works in question.

THE second document just issued (Brockhaus, Leipzig) in connection with the "Riebeck'sche Niger Expedition," is like the first, which dealt with the Fulah language, mainly philological. The chief contents are: "Specimens of the Language of Ghāt in the Sahara, with Haussa and German Translations," by the learned leader of the expedition, Herr Gottlob Adolf Krause. The Ghāt being merely a variety of the Mashagh (Berber, or Western Hamitic), no special grammar was needed of a language which has already been somewhat fully elucidated by Barth, Hanoteau, Prof. Newman, and Stanhope Freeman. But these texts in the Arabic and Roman characters with interlinear German translations, and free Haussa and German versions, will be accepted as a boon by students of the languages of Sudan and North Africa. The accompanying "Anmerkungen" throw

considerable light on many obscure grammatical points, besides bringing into still closer relationship the Semitic and Hamitic groups, whose fundamental affinity is daily becoming more and more obvious. The widespread relations of what Herr Krause calls the "Haussa-Musukanische Sprach-Stamm" (Haussa-Musgu linguistic family) are also elucidated, and the curious principle of vowel harmony prevalent in this group for the first time clearly explained. It differs entirely from the Bantu, which is initial, and also from the Finno-Tatar, inasmuch as in the latter the vowels of the agglutinated postfixes conform to that of the root, which is never modified, whereas in Haussa-Musgu the root-vowel conforms to that of the postfix, and is consequently subject to constant change. Thus: *a-dara* = he loves; *e-diri-kini* = he loves you, where the preceding pronominal and root-vowel *a* has been throughout modified to *e* and *i* by the influence of the following *i* of the pronominal suffix *kini*. The introduction contains many interesting details on the history of the Ghât oasis, which most of our readers will learn for the first time was incorporated in the Turkish Empire some ten years ago. Here also some fresh light is thrown on the origin of the national or imposed names Mashagh (Imoshagh), Tuarek, Berber, Moor, Tibu, Fezzan, and Ghât. For his munificence in undertaking the publication of these "Mittheilungen" without the remotest prospect of any pecuniary returns, Dr. Emil Riebeck has earned the lasting gratitude of the scientific world.

IN the June number of *Timehri*, a journal steadily growing in scientific importance and general usefulness, the accomplished editor, Mr. E. F. Im Thurn, continues his valuable "Notes on West Indian Stone Implements." The title of these papers is now enlarged by the additional words, "and other Indian Relics," so as to include all objects, whether of stone, shell, bone, or clay, which are often found associated together in such a way as to render their separate treatment almost impossible. This enlargement of the subject cannot fail to be appreciated by ethnologists, who will here find much instructive matter lucidly arranged, and illustrated by eleven plates containing thirty-five fac-similes of stone and shell implements, and twenty-one of Carib pottery. The first group of objects belong to Sir Thomas Graham Briggs, of Barbados, who has placed his fine collection at the disposal of Mr. Im Thurn, at the same time generously providing the means for the due illustration of the series. The second group forms part of a quantity of native (Carib) pottery recently discovered on the Enmore Plantation, west coast of Demerara. The urgent necessity of encouraging collections of this sort before all have disappeared, like the natives themselves, before the advance of civilised man, is made evident by the statement that a large heap of shell implements lately found in the parish of St. James, Barbados, were carted away "to macadamise a road." Other attractive papers in this number are: "Bush-Notes of a Huntsman," by M. McTurk; "The Mountains of the West Indies," by T. P. Poter; and "Essequibo, Berbice, and Demerara under the Dutch" (continued), by the Editor.

THE following announcements are made by Mr. Edward Stanford:—"A Parliamentary County Atlas of England and Wales," containing maps of all the counties engraved on a uniform scale. This atlas includes as a distinctive feature a series of physical, statistical, and administrative maps of England and Wales and of London. The rainfall, barometric pressure, temperature of the air and of the seas around our coasts are shown for every month of the year; a river basin map, with an accompanying table giving the area of each river basin and the length of the chief water channel in each basin; an orographic map, indicating by colours the plains, hills, and mountains, with much other information of interest. A short description of each county accompanies the maps. "A Trigonometrical Survey of the Island of Cyprus," executed by command of His Excellency Major-General Sir R. Biddulph, K.C.M.G., C.B., R.A., High Commissioner, under the direction of Major H. H. Kitchener (Captain R.E.), Director of Survey, assisted by Lieut. S. C. N. Grant, R.E. The map is drawn to a scale of one inch to one statute mile = 1 : 63,360, the scale of the Ordnance Survey of the United Kingdom; it has been engraved on fifteen copper plates, and will be printed on imperial sheets, forming, when bound, an atlas measuring 15 inches by 22 inches, or, when mounted together, one map measuring 12 feet 6 inches by 7 feet. "A School Map of British Colonies and Possessions," drawn on a uniform scale, and agreeing in style, size, and price with the other maps of Stanford's Series. Also a second and much enlarged edition of the "Geology of Weymouth, Portland, and the Coast of Dorset," with coloured geological map, section, and photographic frontispiece; "The Countries of the World," the fifth and concluding book of the Geographical Readers, by Charlotte M. Mason, containing Asia, Africa, America, and Australasia; the concluding volume of Stanford's "Compendium of Geography and Travel—Europe," by F. W. Rudler, F.G.S., and G. G. Chisholm, B.Sc., edited by Sir Andrew C. Ramsay, LL.D., F.R.S., with ethnological appendix by A. H. Keane, M.A.I., illustrated with fifteen maps and numerous cuts; "The Monuments of Athens: a Historical and Archæological Description," by Pomagistes G. Kastromenos, translated from the Greek by Agnes Smith, author of "Glimpses of Greek Life and Scenery"; "The Visitor's Guide to Orvieto," by J. L. Bevir, M.A., Assistant Master at Wellington College.

E. AND F. N. SPON have in the press "Candles, Soap, and Glycerine," a practical treatise on the materials used and processes involved, by Mr. W. Lant Carpenter, B.Sc.; "A Text-Book of Tanning," embracing the theory and practice of preparing and dyeing all kinds of leather, by H. R. Procter, of Lowlights Tanneries, Examiner in Tanning to the Guilds Institute; "On Portable Railways," by Mr. Paul Decanville, M.I.M.E.; "History and Description of the Manchester Water-Works," by J. F. La Trobe Bateman, F.R.SS. Lond. & Edin., Past President of the Institution of Civil Engineers, F.G.S., &c.; "An Electrical Supplement to the Pocket-Book of Engineering Formulæ," by G. L. Molesworth, M.I.C.E., M.I.M.E., Consulting Engineer to the Government of India for State Railways; "On the Analysis of Iron and Steel," by T. Bayley, author of "The Chemist's Pocket-Book"; a new edition of "The Modern Practice of Sinking and Boring Wells," by Mr. Ernest Spon, Assoc.Mem.Inst.C.E., Spon's "Mechanics' Own Book," a manual for handicraftsmen and amateurs; "Sanitary Protection," a course of lectures delivered in the Theatre of the Royal Dublin Society, 1884, by W. Kaye Parry, M.A.

PHYLLOXERA is making steady progress in the Rhenish vineyards it seems. The pernicious insect has now been found on the right bank of the river, in the vineyards of Castle Ockenfels near Linz, where over 100 acres are infected. State aid has been asked for at Berlin, as the occurrence of the pest near Linz is far more serious than that in the Ahr Valley.

A TUNNEL, measuring about 5000 feet in length, and constructed at least nine centuries before the Christian era, has just been discovered by the Governor of the island of Samos. Herodotus mentions this tunnel, which served for providing the old seaport with drinking water. It is completely preserved, and contains water tubes of about 25 centimetres in diameter, each one provided with a lateral aperture for cleansing purposes. The tunnel is not quite straight, but bent in the middle; this is hardly to be wondered at, as the ancient engineers hardly possessed measuring instruments of such precision as those constructed nowadays.

THE *Globus* reports the discovery of the ruins of an ancient city near Samarkand. They are situated upon a hill, which was

doubtless a fortress formerly. Remains of utensils and human bones have also been found. According to Arabian sources the large city of Aphrosiab existed there in the time of Moses; it was the royal residence, and the king's castle stood on the hill, and was provided with subterranean corridors. The result of the excavations show that the ruins are indeed those of a very ancient city. The various depths, however, differ widely; in the lower ones fine glass objects are found, which are quite absent from the upper ones; the lowest layers contain remains of a very primitive nature, *i.e.* coarse implements of clay and flint. The excavations are being continued. News from Turkestan announces the discovery of another ancient city, Achsy, on the right bank of the Amu Darya. Remains of brick walls and other buildings are said to be visible in considerable numbers.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. A. F. M. Smith; a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mr. G. S. Malet Barrow; a White-backed Piping Crow (*Gymnorhina leuconota*) from Australia, presented by Mr. F. Larkworthy; two Loggerhead Turtles (*Thalassochelys caouana*) from the Mediterranean, presented by Mr. Allan McGregor; a Common Chameleon (*Chameleon vulgaris*) from North Africa, presented by Mr. A. R. Rogers; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Capt. H. Mends; a Brown Mud Frog (*Pelobates fuscus*), European, presented by Mr. Claude Russell; a Sulphur-breasted Toucan (*Ramphastos carinatus*) from Mexico, a Macaque Monkey (*Macacus cynomolgus* ♂) from India, a Robben Island Snake (*Coronella phocarum*) from South Africa, deposited; a Collared Fruit Bat (*Cynonycteris collaris*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE APPROACHING APPEARANCE OF ENCKE'S COMET.—It may be hoped that, as at the last return of this comet in 1881, an accurate ephemeris for its reappearance, which is now at hand, may be issued from the Imperial Observatory at Pulkowa. According to the mean motion, assigned by the calculations of Dr. Backlund at perihelion passage in 1881, the comet would be again in perihelion (perturbations neglected) about March 7·5 G.M.T., 1885, so that as the effect of planetary attraction will be small during the actual revolution, the comet's track in the heavens will not greatly differ from that it followed in 1852, when the perihelion passage occurred on March 14. It was first observed in that year by Dr. Vogel, at Mr. Bishop's Observatory in the Regent's Park on the evening of January 9, a refractor of 7 inches aperture being employed; at this time its distance from the sun was 1·35, and that from the earth 1·55, so that the intensity of light expressed in the usual manner was 0·23. At the return in 1875, when the perihelion passage took place on April 13, the comet was detected at the Observatory of Marseilles by M. Stephan, on the evening of January 27, distant from the sun 1·50, and from the earth 1·98, the theoretical intensity of light being therefore 0·113, or only half that at the comet's discovery in 1852. There appears to be a probability that with the large instruments now so comparatively common in observatories, the comet may be observed at a greater distance from the sun than in that year, and possibly during the absence of moonlight in November. If we assume March 7·5 for the date of perihelion passage, and bring up the longitudes in Dr. Backlund's orbit of 1881 to the beginning of 1885, we shall have the following positions of the comet at Greenwich midnight:—

1884		R.A. h. m.		N.P.D. ° ′		Distance from Earth		Distance from Sun		Intensity of Light
Nov. 5	...	23 2·1	...	82 24	...	1·310	...	2·043	...	0·140

Encke did not continue the ephemeris in 1852 beyond the dat of perihelion passage, but if we calculate from his elements fo April 19·5 (the day of the new moon), we find the comet's plac to have been in R.A. 342° 55′, N.P.D. 109° 22′, its distanc from the sun 0·89, and from the earth 0·95, or the intensity o light 1·41; it would rise at the Cape about 14h. 1m., and mus therefore have been readily observable. We may expect tha in 1885 observations will be made in the southern hemispher after perihelion passage.

VARIABLE STARS.—Mira Ceti is now close upon a minimum a phase of which there are not too many observations: its mag nitude is usually about 8·5 on Bessel's scale. χ Cygni wil probably be at minimum about November 15: the mean of th last five periods, according to the observations of the late Prof Julius Schmidt, is 408·2 days, and 1880 May 31·2 may be take as a mean maximum epoch. A maximum of the fiery-looking variable R Leonis may be expected about December 10. R Leporis will probably be at minimum at the beginning of January.

SOUTHERN BINARIES.—There are two southern double-stars which appear to deserve much closer observation than they have yet received on the score of their probable binary character and rapid motion. They are:—

The positions are brought up to 1885·0 from the Paramatta Catalogue.

ON THE SEAT OF THE ELECTROMOTIVE FORCES IN THE VOLTAIC CELL

AT the Montreal meeting of the British Association a discu sion on the above subject was opened by Prof. O. J. Lodg Copies of the following notes were distributed to the membe present by the opener of the discussion, together with the a companying letter. As it has been suggested that their repr duction here would be of service, we willingly give them place.

University College, Liverpool, July 29th, 1884

The following set of statements are privately issued by n solely with the object of securing attention to definite points the discussion on Contact Electricity, at Montreal, which I ha been instructed by the Sub-Committee to open. They a numbered for convenience of reference. I have no authori whatever for appending the names I have appended to some the statements; and in general the whole thing is merely statement of my own personal belief. At the same time t wording is carefully chosen and is intended to be correct detail, and the views indicated I have held with greater or le clearness for some seven years. I should have small hesitati in believing these views to be true, were it not that I fear th are at variance with those of Sir Wm. Thomson. It is in spirit of presumption, but simply in order more easily and d tinctly to elicit the truth, that I have ventured thus to rec them, and I am very willing to modify all or any of them ground shown. It may be hoped that the discussion at Montr will result in a substantial basis of agreement with regard to t elementary and long-debated matter. OLIVER J. LODGE

I.—ORTHODOX STATEMENTS BELIEVED BY O. J. L. TO TRUE IN THE FORM HERE SET DOWN

A.—Volta

1. Two metals in contact ordinarily acquire opposite char for instance, clean zinc receives a positive charge by contact copper, of such a magnitude as would be otherwise produc under the same circumstances by an E.M.F. of ·8 volt.

2. This apparent contact E.M.F. or "Volta force" is ind pendent of all other *metallic* contacts wheresoever arrange hence the metals can be arranged in a numerical series such th the "contact force" of any two is equal to the difference of t numbers attached to them, whether the contact be direct through intermediate metals. But whether this series chang when the atmosphere, or medium surrounding the met changes is an open question: on the one side are experimen of De la Rive, Brown, Schultze-Berge; on the other side, Pfaff, Pellat, von Zahn. It certainly changes when the fr metallic surfaces are oxidised or otherwise dirty. And in gener

this "Volta force" is very dependent on all non-metallic contacts.

3. In a closed chain of any substances, the resultant E.M.F. is the algebraic sum of the Volta forces measured electrostatically in air for every junction in the chain; neglecting magnetic or impressed E.M.F. [Verified most completely by Ayrton and Perry.]

B.—Thomson

4. The E.M.F. in any closed circuit is equal to the energy conferred on unit electricity as it flows round it.

[Neglect magnetic or impressed E.M.F. in what follows.]

5. At the junction of two metals any energy conferred on, or withdrawn from, the current, must be in the form of heat. At the junction of any substance with an electrolyte, energy may be conveyed to or from the current at the expense of chemical action as well as of heat.

6. In a circuit of uniform temperature, if metallic, the sum of the E.M.F. is zero by the second law of thermodynamics; if partly electrolytic, the sum of the E.M.F. is equal to the sum of the energies of chemical action going on per unit current per second.

7. In any closed conducting circuit the total intrinsic E.M.F. is equal to the sum of the chemical actions going on per unit electricity conveyed ($\Sigma_e J\theta e$), diminished by the energy expended in algebraically generating reversible heat.

8. The locality of any E.M.F. may be detected, and its amount measured, by observing the reversible heat or other form of energy there produced or absorbed per unit current per second. [This is held by Maxwell, but possibly not by Thomson, though its establishment is due to him.]

II.—Statements believed by O. J. L. to be false though orthodox

9. Two metals in air or water or dilute acid, but not in contact, are practically at the same potential. [Sir Wm. Thomson, Clifton, Pellat.]

10. Two metals in contact are at seriously different potentials (*i.e.* differences of potential greater than such milli-volts as are concerned in thermo-electricity). [This is held by nearly everybody.]

11. The contact force between a metal and a dielectric, or between a metal and an electrolyte, is small. [Ayrton and Perry, Clifton, Pellat, and probably Sir Wm. Thomson].

III.—Statements believed by O. J. L. to be true though not orthodox

12. A substance immersed in any medium tending to act upon it chemically will (unless it is actually attacked) be at a different potential to the medium in contact with it, positive if the active element in the medium is electro-positive, negative if the active element is electro-negative.

13. The above difference of potential can be calculated approximately from the potential energy of combination between the substance and the medium, the energy being measured by compelling the combination to occur and observing the heat produced per amount of substance corresponding to one unit of electricity.

14. In addition to this contact force, due to potential chemical action or chemical strain, there is another which is independent of chemical properties, but which seems to be greatest for badly-conducting solids, and which is in every case superposed upon the former contact force, the two being observed together and called the Volta effect. Very little is known about this latter force except in the case of metals; and in these it varies with temperature, and is small. In the case of non-metals it is often much larger than the chemical contact force.

15. The total contact force at any junction can be experimentally determined by measuring the reversible energy developed or absorbed there per unit quantity of electricity conveyed across the junction. [Practical difficulties, caused by irreversible disturbances, being supposed overcome.]

16. In a chain of any substances whatever, the resultant E.M.F. between any two points is equal to the sum of the true contact forces acting across every section of the chain between the given points (neglecting magnetic or impressed forces).

17. In a closed chain the sum of the "Volta forces," measured electrostatically in any (the same) medium, is equal to the sum of the true contact forces, whether each individual Volta force be equal to each individual true force or not.

18. Wherever a current flows across a seat of E.M.F., there it must gain or lose energy at a rate numerically equal to the E.M.F. multiplied by the strength of the current.

Development of the above and Special Application to Metals.

19. A metal is not at the potential of the air touching it, but is always slightly below that potential by an amount roughly proportional to its heat of combustion, and calculable, at any rate approximately, from it. For instance, clean zinc is probably about 1·8 volts below the air, copper about ·8 volts below, and so on. If an ordinary oxidising medium be substituted for "air" in the above statement it makes but little difference.

20. Two metals put into contact reduce each other instantly to practically the same potential, and consequently the most oxidisable one receives from the other a positive charge, the effect of which can be observed electrostatically.

21. There is a slight true contact force at the junction of two metals which prevents their reduction to *exactly* the same potential, but the outstanding difference is small, and varies with temperature. It can be measured thermo-electrically by the Peltier effect, but in no other known way. It is probably entirely independent of surrounding media, metallic or otherwise.

22. If two metals are in contact the potential of the medium surrounding them is no longer uniform: if a dielectric it is in a state of strain, if an electrolyte it conveys a current.

23. In the former case the major part of the total difference of potential is related closely to the difference of the potential energies of combination, and is approximately calculable therefrom. In the latter case the total E.M.F. is calculable accurately from the energy of the chemical process going on, minus or plus the energies concerned in reversible heat effects.

24. There are two distinct and independent kinds of series in which the metals (and possibly all solids) can be placed; one kind depends on the dielectric or electrolytic medium in which the bodies are immersed; the other kind depends on temperature. The one is something like the Volta series, but it is really the Volta series minus the Peltier; the other is the Peltier. To reckon up the total E.M.F. of a circuit we may take differences of numbers from each series and add them together.

IV.—Brief Summary of the Argument

25. Wherever a current gains or loses energy, *there* must be a seat of E.M.F.; and conversely, wherever there is a seat of E.M.F., a current must lose or gain energy (that is, must generate or destroy some other form of energy, chemical, thermal, or other) in passing it.

26. A current gains no energy (*i.e.* destroys no heat) in crossing from copper to zinc, hence there is no appreciable E.M.F. there.

27. When a current flows from zinc to acid, the energy of the combination which occurs is by no means accounted for by the heat there generated, and the balance is gained by the current; hence at a zinc-acid junction there must be a considerable E.M.F. (say at a maximum 2·3 volts).

28. A piece of zinc immersed in acid is therefore at a lower potential than the acid, though how much lower it is impossible to say, because no actual chemical action occurs. [If chemical action does occur, it is due to impurities, or at any rate to local currents, and it is of the nature of a disturbance.]

29. A piece of zinc, half in air and half in water or acid, causes no great difference of potential between the air and the water (Thomson, Clifton, Ayrton and Perry, &c.), consequently air must behave much like water.

30. If the air were slightly positive to the water, as it is (Hankel), it might mean that the potential energy of combination of air with zinc is slightly greater than that of water, or it might represent a difference in the thermo-electric contact forces between zinc and air, and zinc and water, or it might depend on a contact force between air and water. [If such a contact force between air and water exists, it is obviously of great importance in the theory of atmospheric electricity, for the slow sinking of mist globules through the air would render them electrical.]

31. Condenser methods of investigating contact force no more avoid the necessity for unknown contacts than do straightforward electrometer or galvanometer methods; the circuit is completed by air in the one case and by metal in the other, and the E.M.F. of an air contact is more hopelessly unknown than that of a metal contact.

32. All electrostatic determinations of contact force are really determinations of the sum of at least three such forces, none of which are knowable separately by this means.

33. The only direct way of investigating contact force is by the Peltier effect or its analogues. [Maxwell.]

34. Zinc and copper in contact are oppositely charged, but are not at very different potentials: they were at different potentials before contact, but the contact has nearly equalised them.

[Certain portions of these statements which may appear wildly hypothetical, such as 13, are to be justified by figures. The justification is not complete, for lead and iron are untractable, but it does not affect the main position.]

THE AMERICAN ASSOCIATION

We are indebted to the courtesy of the Editor of *Science* for the following reports of the Sectional proceedings of the American Association.

In the Section of Physics a paper was read on "The Relation of the Yard to the Metre," by Prof. William A. Rogers, who has given his life to perfecting the construction and the testing of standards of length, and the result of this his latest investigation is that the metre is 39·37027 inches in length. One of the most important physical measurements is that of the wave-length of light of any given degree of refrangibility, and this determination is best made by means of the diffraction grating. On account of the extensive use of the magnificent gratings constructed by Prof. Rowland for this purpose, Prof. Rogers instituted an investigation to determine the coefficient of expansion of the speculum-metal used in the construction of these gratings. He also noted that from its homogeneity, fineness of grain, and non-liability to tarnish, this speculum-metal is peculiarly suitable for constructing fine scales, though its extreme brittleness is an objection to its use for large scales.

Prof. Rowland stated that he proposed to construct scales on his ruling-engine which would enable the physicist at any time, by purely optical means, and without knowing the coefficient of expansion of the metal or its temperature, to obtain the value of the length of the scale in terms of the wave-length of any given ray of light. These scales were simply to be straight pieces of speculum-metal ruled with lines just as an ordinary grating, except that the length of the lines is to be only about one centimetre, every one-hundreth line being somewhat longer than its neighbours: the whole ruled slip is to be one decimetre in length. From the manner of ruling, it will be easy to count the whole number of lines in the length of the strip, and then by a simple use of the scale as a grating, in a suitable spectrometer, the whole length may be immediately found at any time in terms of any specified wave-length of light. In some forms of telephones and in the microphone the action depends on the change in resistance of a small carbon button on being subjected to pressure. There has been much discussion as to whether this diminution of the resistance with pressure is due to a change in the resistance of the carbon itself, or simply to the better contact made between the carbon and the metallic conductor when the pressure is applied.

Prof. Mendenhall has carried out some experiments to determine the question; and one of his methods of experimenting—that with the hard carbons—appears to point conclusively in favour of the theory that the resistance of the carbon itself is altered by pressure. The experiments made by him on soft carbon are open to criticism, though they also point to the change taking place *in* the carbon. Prof. Mendenhall finds that the resistance is not simply proportional to the pressure, and thinks that by increasing the pressure a point of maximum conductivity would be reached where there would be no change in resistance for a small change in pressure.

Prof. A. Graham Bell, the inventor of the telephone, read a paper giving a possible method of communication between ships at sea. The simple experiment that illustrates the method which he proposed is as follows:—Take a basin of water, introduce into it, at two widely-separated points, the two terminals of a battery circuit which contains an interruptor, making and breaking the circuit very rapidly. Now at two other points touch the water with the terminals of a circuit containing a telephone. A sound will be heard, except when the two telephone terminals touch the water at points where the potential is the same. In this way the equipotential lines can easily be picked out. Now, to apply this to the case of a ship at sea: Suppose one ship to be provided with a dynamo-machine generating a powerful current, and let one terminal enter the water at the prow of the ship, and the other be carefully insulated, except at its end, and be trailed behind the ship, making connection with the sea at a considerable distance from the vessel; and suppose the current be rapidly made and broken by an interruptor; then the observer on a second vessel provided with similar terminal conductors to the first, but having a telephone instead of a dynamo, will be able to detect the presence of the other vessel even at a considerable distance; and by suitable modifications the direction of the other vessel may be found. This conception Prof. Bell has actually tried on the Potomac River with two small boats, and found that at a mile and a quarter, the farthest distance experimented upon, the sound due to the action of the interruptor in one boat was distinctly audible in the other. The experiment did not succeed quite so well in salt water.

Prof. Trowbridge then mentioned a method which he had suggested some years ago for telegraphing across the ocean without a cable; the method having been suggested more for its interest than with any idea of its ever being put in practice. A conductor is supposed to be laid from Labrador to Patagonia, ending in the ocean at those points, and passing through New York, where a dynamo-machine is supposed to be included in the circuit. In Europe a line is to extend from the north of Scotland to the south of Spain, making connection with the ocean at those points; and in this circuit is to be included a sensitive galvanometer. Then any change in the current in the American line would produce a corresponding change in current in the European line; and thus signals could be transmitted.

Mr. W. H. Preece then gave an account of how such a system had actually been put into practice in telegraphing between the Isle of Wight and Southampton during a suspension in the action of the regular cable communication. The instruments used were a telephone in one circuit, and in the other about twenty-five Leclanché cells and an interruptor. The sound could then be heard distinctly; and so communication was kept up until the cable was again in working order. Of the two lines used in this case, one extended from the sea at the end of the island near Hurst Castle, through the length of the island, and entered the sea again at Ryde; while the line on the mainland ran from Hurst Castle, where it was connected with the sea, through Southampton to Portsmouth, where it again entered the sea. The distance between the two terminals at Hurst Castle was about one mile, while that between the terminals at Portsmouth and Ryde amounted to six miles.

A few years ago Mr. E. H. Hall, then a student at the Johns Hopkins University, taking a thin strip of gold-leaf through which a current of electricity was passing, and joining the two terminals of a very sensitive galvanometer to two points in the gold-leaf, one on one edge, and the other on the other, choosing the points so exactly opposite that there was no current through the galvanometer, found that on placing the poles of a powerful electro-magnet, one above and the other below the strip of gold-leaf, he obtained a current through the galvanometer, thus indicating that there was a change in the electric potential, due to the action of the magnet. Mr. Hall explains this change by supposing the rotation of the equipotential lines in the conductor about the lines of magnetic force. This explanation has been brought into question by Mr. Shelford Bidwell, who attempts to explain the action thus: the magnetic force acting on the conductor carrying the current would cause the conductor to be moved sideways, were it free to move; but, since it is held by clamps at the ends, the magnetic force acting upon it brings it into a state of strain, one edge being compressed and the other stretched; and Mr. Bidwell supposes the whole Hall effect to be due to thermal actions taking place in consequence of this unsymmetrical state of strain. Prof. Hall, who is now at Harvard, has made some careful experiments to test this explanation of Mr. Bidwell. He used not only gold-leaf, but strips of steel, tinfoil, and other metals, and clamped them sometimes at both ends, sometimes in the middle, and sometimes only at one end; and in all cases the action was the same, with the same metal, irrespective of the manner of clamping. This was strong evidence against Mr. Bidwell's position.

Sir William Thomson suggested, as a further test to bring about the state of strain, which Mr. Bidwell supposes to be the primary cause of the action, by purely mechanical means, bring-

ing pressure to bear on one side or the other, and seeing whether the action obtained is at all commensurate with the action found by Mr. Hall.

Prof. Hall then discussed an experiment by which Mr. Bidwell had obtained a reversal of the effect, and showed that the reversal was only apparent, and that when carefully examined the results of Mr. Bidwell's experiments were best satisfied by the theory of the rotation of the equipotential surfaces about the lines of magnetic force.

Sir William Thomson spoke of the discovery of Mr. Hall as being the most important made since the time of Faraday. He favoured Mr. Hall's explanation, though he considers Mr. Bidwell's suggestion as very important, and thinks that it will very likely be found that both the Hall effect and thermal effects have a common cause, rather than that one is to be taken to explain the other. He showed also that the mathematical examination of the subject indicates three relations to be investigated,—first, the relation of thermal force to the surfaces of equal rate of variation of temperature; second, the relation of electric current to the equipotential surfaces; third, the relation of the thermal flow to isothermal surfaces. The second of these is that investigated by Mr. Hall, who has found that under the conditions mentioned the lines of flow are *not* perpendicular to the equipotential surfaces. There remains, therefore, "work for two more Halls," in either proving or disproving the existence of the analogous actions in these other two cases. Sir William Thomson also suggested the following exceedingly interesting mechanical illustration or analogue of Hall's effect. Let us be living upon a table which rotates uniformly for ever. A narrow circular canal is upon this table, concentric with the axis of rotation of the table, and nearly full of water. After a while the water will acquire the same velocity of rotation as the table, and will come to a state of equilibrium. The outer edge of the water in the canal will then stand a little higher than the inner edge. Let us now apply a little *motive* force to the water, and by means of a pump cause it to flow in the canal in the same direction in which the table is already rotating: it is evident that it will stand higher on the outer edge, and lower on the inner edge of the canal, than before. But, should we cause it to flow in the opposite direction to the motion of the table, it will stand lower on the outer edge, and higher on the inner edge, than in its position of equilibrium. The experiment made by Mr. Shelford Bidwell may also be illustrated by putting a partition in the canal so as to divide it into two circular concentric troughs, and make a little opening in the partition at some point; then taking two points near the opening in the partition, one in one trough and one in the other, if they are very close to the partition, the point in the outer trough will be at a *lower* level than that in the inner one; but if they are not close to the partition, but one is taken close to the outer edge of the outer trough and the other close to the inner edge of the inner trough, then the point in the outer trough will be at a *higher* level than that in the inner trough, though the difference in level will be only about half of what it would have been had there been no partition separating the canal into two troughs.

Prof. Forbes called attention to the fact that the classification of the metals according to their thermo-electric qualities gives not only exactly the same division into positive and negative, but that the very *order* obtained in that way corresponds to that obtained by classifying according to the Hall effect, except *possibly* in the case of aluminium.

In the Section of Mathematics and Astronomy the first paper read was by Prof. E. C. Pickering, upon the colours of the stars. The need of exact photometric measurement of different parts of their spectra was first pointed out, and the author then described a very ingenious method of accomplishing this. In the telescope tube, a little beyond the focal plane, is a direct-vision prism, so set as to give a spectrum extended in declination; and on the preceding side of this prism is placed a piece of plane glass, whose edges are so ground that, when a small portion of the following side of the cone of rays falls upon it, it gives a small white ghost, just preceding the spectrum and always opposite the same wave-length. In the focal plane is one of Prof. Pritchard's neutral-tint wedge photometers, and behind it a thin metal diaphragm with four long, narrow slits parallel to the equatorial motion; so that, when the spectrum transits behind them, four little stars—a red, yellow, blue, and a violet—shine through these slits, and the time of the disappearance of each, as they move towards the thicker edge of the wedge, measures its brightness. From these times may be deduced the magnitude and colour curve of the star. To fix the same wave-lengths for each observation, the little white ghost is adjusted upon one of two parallel wires which project out beyond the preceding side of the diaphragm. For a succeeding transit, the ghost is adjusted upon the other wire, half a slit-interval distant, and thus eight points of the spectrum are photometrically measured.

Prof. Young of Princeton spoke very highly of the ingenuity and effectiveness of the device, especially for the systematic measurement of a large number of stars. He pointed out, however, what might be a source of error, viz. the different sensitiveness of different observers' eyes to different colours, so that they would probably observe the times of disappearance of the four coloured stars slightly relatively different.

The next paper, by Prof. Daniel Kirkwood, discussed the question whether the so-called "temporary stars" may be variables of long period, referring to the sometimes-claimed identity of the temporary stars 945 and 1264, with the well-known Tycho Brahe's star, which blazed forth in Cassiopeia in 1572, and whose position is pretty closely known from his measures. The conclusion reached was, that on account of the sudden apparition of the temporary stars, the short duration of their brightness, and the extraordinary length of their supposed periods, they should be considered as distinct from variables.

Prof. Mansfield Merriman, the author of the well-known treatise on "Least Squares," proposed a criterion for the rejection of doubtful observations, founded upon Wagen's demonstration of the law of frequency of error, which was simpler than Pierce's or Chauvenet's. It involves, however, a determination of what is the unit of increment between errors of different sizes, a thing difficult to determine in very many cases.

Prof. Pickering then read another paper upon systematic errors in stellar magnitudes, showing, without any question, that the magnitudes of all the star-catalogues, from that of Ptolemy down to the great work of Argelander in the *Durchmusterung*—all depending upon eye-estimates—are systematically affected by being in, or close to, the Milky Way; they all being estimated too faint, and the error amounting to about half a magnitude in the Milky Way itself. This arises from the brightness of the background upon which the star is viewed. In the Harvard photometry measures, this source of error is avoided, since, in the comparison of each star with the Pole-Star, the two fields are superposed, and their added brightness affects both stars alike.

Prof. M. W. Harrington, Director of the Ann Arbor Observatory, read a paper upon the asteroid ring. He showed that the representative average orbit would be an ellipse of small eccentricity, with semi major axis equal to about 2·7 times that of the earth, and inclined to the plane of the ecliptic about 1°; and that, in the progressive discovery of these small bodies, the average mean distance had gradually increased, but now seemed to have reached its limit. On the assumption that the surfaces of all the asteroids have the same reflecting power as Vesta, Prof. Harrington reaches the conclusion that the volume of Vesta is about 5/17 that of all these 230 bodies put together, and that Vesta and Ceres together form almost one-half the total volume.

Prof. Rogers, of the Harvard College Observatory, read two papers. The first, upon the magnitude of the errors which may be introduced in the reduction of an observed system of stellar co-ordinates to an assumed normal system by graphic methods, showed a great amount of laborious research, and was a good illustration of the vast amount of monotonous work necessary in the present stage of astronomical observation in order to reach the highest degree of accuracy attainable by the search for and elimination of minute systematic errors. His next paper was upon the original graduation of the Harvard College meridian circle *in situ*. This described a method of turning a meridian circle through any desired constant arc up to about 30° without any dependence upon the circle and reading microscopes, effected by means of an arm swinging between fixed stops, and clamping to a circular ring on the axis by an electro-magnetic clamp. With this Prof. Rogers claimed to be able to set off a constant arc through as many as five thousand successive movements of the clamping arm. The ingenious method suggested and carried out by Mr. George B. Clark, of the firm of Alvan Clark and Sons, of grinding the clamping circle to a perfect circular form while the telescope was swung round in its Y's was

fully described, and also Prof. Rogers' method of arresting the momentum of the telescope at the stops by water-buffer plungers. The great advantage of thus being able to set off a constant arc independent of the circle and microscopes was pointed out, with especial reference to the investigation of division errors and flexure of circle, and also to the division of the circle itself *in situ ; i.e.* mounted on its axis and turning on its pivots.

Prof. Young called attention to the necessity of guarding against expansion and contraction of the bar holding the stops, due to radiation from the observer's body.

Mr. S. C. Chandler, Jun., of the Harvard College Observatory, gave the results of observations and experiments with an "almucantar" of four inches' aperture, a new instrument devised by Mr. Chandler, which seems to be of remarkable accuracy, and promises to furnish an entirely new and independent method of attacking some of the most important problems in exact observational astronomy. The instrument consists of a telescope and vertical setting-circle, which can be clamped at any zenith-distance, and is supported on a rectangular base which floats in a rectangular trough of mercury, the whole turning round a vertical axis so as to observe in any azimuth ; these observations being simply the times of transit of any heavenly body over a system of horizontal wires in the field. The observations thus far have been entirely upon stars, and all at the apparent zenith-distance of the pole. After some very small periodic variations in the zenith-distance pointing had been traced to changes of temperature, and had been removed by sawing through the wooden bottom of the mercury trough, the instrument showed an astonishing constancy in this zenith-distance pointing, extending over weeks at a time, and far exceeding the constancy of the corrections to the best fundamental instruments of our observatories.

A paper was read by Mr. Chandler, upon the colours of variable stars. Showing, first, that most of the variables were *red*, he described some fairly satisfactory methods which he had used to measure the *degree* of redness of all the periodic variables ; and then, plotting a series of points whose abscissæ represented the *length* of the periods, and ordinates the *degree of redness*, their agreement with a curve making a very decided angle with the axis of abscissæ brought out without question the remarkable law that *the redder the star the longer is its period of variability.* In discussing any theory of variable stars, Mr. Chandler pointed out that Zöllner was the only one who had thus far taken into account two laws already known, viz. (1) that they are generally *red ;* (2) that they *increase* in brightness *much more rapidly* than they *decrease ;* and now, in any further theory, this new third law must have a place, viz. that the *redder* they are the *longer* is their period.

Dr. R. S. Ball, Astronomer-Royal for Ireland, read a paper upon the ruled cubic surface known as the cylindroid, whose equation is

$$z(x^2 + y^2) - 2mxy :$$

Mr. W. S. Auchencloss of Philadelphia exhibited a balancing machine for finding the centre of gravity of any number of different weights distributed along a line, which seemed to be of excellent construction, extremely easy and rapid in manipulation, and quite sensitive. In connection with a time-scale of 365 days at one side, it was shown how rapidly a complicated system of business accounts could be settled, and how it could be applied to various engineering problems.

Prof. J. H. Gore, of the U.S. Geological Survey, read a paper upon the geodetic work of the U.S. Coast and Geodetic Survey.

The next paper was by Mr. J. N. Stockwell of Cleveland, upon an analysis of the formula for the moon's latitude as affected by the figure of the earth. In this Mr. Stockwell claimed that Laplace's formula for expressing this was wrong ; the question turning upon an approximate integration of a differential equation, which he claimed to show was wrong by separating into two terms a single one which expressed the difference of two effects, which, thus evaluated separately, became either indeterminate or of an impossible amount.

Prof. J. C. Adams of Cambridge, England, made some comments upon Mr. Stockwell's paper, speaking in high terms of the general work which Mr. Stockwell had done in the difficult subject of the lunar theory ; but from such conclusions and methods as those brought forward in this particular case he said he must express his total dissent. He then pointed out that this equation was, to begin with, only an approximation ; that, before it could be treated at all as a rigorous one, many other small terms must be included ; that, further, its integration was only an approximation ; and that in this case any separation into terms, which, on a certain approximate assumption, became either indeterminate or very large, was of no value as a test of the equation.

Prof. Ormond Stone, Director of the Leander McCormick Observatory of the University of Virginia, gave an elaborate description of that Observatory, now approaching completion, and to be devoted entirely to original research. The telescope, which will soon be mounted, is the twin in size of the Washington 26-inch, and like it in most of its details, except that the driving clock is like that of the Princeton 23-inch, with an auxiliary control by an outside clock, and that it has Burnham's micrometer illumination. The Observatory has a permanent fund of 76,000 dollars as a beginning, and 18,000 dollars have been expended in Observatory buildings, and 8000 dollars for the house of the Director. Situated 850 feet above the sea, and on a hill 300 feet above surroundings, the main building, circular in shape, is surmounted by a hemispherical dome 45 feet in diameter. The brick walls have a hollow air-space, with inward ventilation at bottom and outward at top.

Mr. Warner, the builder of the dome, gave an interesting description of the ingenious method of adjusting the conical surfaces of the bearing-wheels, so that they would, without guidance, follow the exact circumference of the tracks ; and then of the adjustment of the guide-wheels, so that the axis of this cone should be exactly normal to the circular track. The framework of the dome consists of thirty-six light steel girders, the two central parallel ones allowing an opening six feet wide. The covering is of galvanised iron, each piece fitted *in situ*, and the strength of the frame is designed to stand a wind-pressure of a hundred pounds per square foot. There are three equal openings with independent shutters, the first extending to the horizon, the second beyond the zenith, and the third so far that its centre is opposite the division between the first and second. The shutters are in double-halves, opening on horizontal tracks, and connected by endless chain with compulsory parallel motion of the ends. The dome weighs twelve tons and a half, and the livering one ton and a half, and a tangential pressure of about forty pounds, or eight pounds on the endless rope, suffices to start it. If this ease of motion continues as the dome grows old, it is certainly a remarkable piece of engineering work.

In the discussion following, Prof. Hough thought he should prefer the old style of single opening extending beyond the zenith

Prof. Stone could not agree with him, the greater extent of opening making it less probable that the dome would have to be moved so far in turning from star to star, and at the same time furnishing better ventilation, and the opportunity for cross-bracing adding strength to the dome. He stated that he should first take up the remeasurement of all the double stars of less than 2″ distance between 0° and − 30°.

The Rev. Father Perry, the Director of the Observatory at Stonyhurst, England, gave the result of late researches on the solar surface, with special reference to evanescent spots.

Mr. Lewis Swift, Director of the Warner Observatory at Rochester, N.Y., read a paper upon the nebulæ, in which he described his method of search for new nebulæ. One very interesting statement of Mr. Swift, to the effect that there had not been a first-rate clear sky since the red glows appeared a year ago following the Krakatoa explosions, bears out the general experience of workers in other observatories, especially those who try to see stars near the sun in the daytime.

An interesting discussion arose as to the much-disputed existence of the nebula round the star Merope in the Pleiades ; the general drift of it being that the nebula no doubt existed, but in order to see it a clear sky was necessary, and a very low power and large field, so that the nebula might be contrasted with darker portions of the same field ; that a large telescope was not necessary, in fact the smaller the better, provided the optical qualities were relatively as good. Mr. Swift said he could always see it under favourable conditions ; and Mr. E. E. Barnard, of Nashville, Tenn., the discoverer of the latest comet, said that before he knew of its existence at all, he picked it up as a supposed comet.

Prof. Adams of Cambridge, England, read a paper upon the general expression for the value of the obliquity of the ecliptic at any given time, taking into account terms of the second order. The difficulties of obtaining a formula for this quantity, on

account of the many varying elements upon which it depends, were clearly explained by a diagram, and the results given of an approximation carried much further than ever attempted heretofore.

Prof. Harkness, in paying a high compliment to the celebrated mathematician and astronomer for these laborious and valuable researches, also expressed a wish that some of the n-dimensional-space mathematicians would follow the example of Prof. Adams, and apply some of their superfluous energy to the unsolved problems in the solar system, which have some direct practical bearing.

Prof. Newcomb, in remarking upon the mass of the moon used in this problem, expressed the opinion that this could be obtained most accurately by observations of the sun, in determining the angular value of the radius of the small circle described by the earth about the common centre of gravity of earth and moon, since this, in his opinion, seemed to be the only constant which could be determined by observation absolutely free from systematic errors, and hence was capable of an indefinite degree of accuracy by accumulated observations; and he asked Prof. Adams's opinion on this point.

The latter replied that he thought the quantity too small for certain accurate determination, almost beyond what could be actually seen by the eye in the instruments used.

Prof. Newcomb admitted, in the case of absolute determinations, the general impossibility of attempting to measure what cannot be seen, but, in the case of differential or relative determinations in which there was no supposed possibility of constant or systematic errors, he advanced the theory, which he had some thought of elaborating more fully at some time, that such determinations might be carried by accumulated observations to a sure degree of accuracy far beyond what can be seen or measured by the eye absolutely.

Prof. Adams hoped he would more fully elaborate and publish this idea, since there was in it an element well worth careful consideration.

Prof. Harkness doubted the sufficient accuracy of meridian observations of the sun, on account of the distortions produced by letting the sun shine full into the instrument; and spoke of the difficulties in the transit of Venus observations from this cause.

Prof. Newcomb replied that he would have to show that this would be periodic with reference to the moon's quarters in order to affect this constant systematically.

Prof. Adams then presented another note upon Newton's theory of atmospheric refraction, and on his method of finding the motion of the moon's apogee.

In the Section of Chemistry papers were read by C. F. Mabery of Cleveland, O., on chloropropiolic acid and some derivatives of acrylic and propionic acids; and by C. W. Dabney on anhydrobenzamidosalicylic acid.

Dr. Springer of Cincinnati exhibited some improved torsion scales and balances. One of these had been used by Prof. F. W. Clarke, and its action was spoken of as being very satisfactory.

Messrs. L. M. Norton and C. F. Presscott read a paper on continuous etherification; and Prof. Monroe detailed results of analyses of an efflorescence on the bricks of some new buildings. It was chiefly sodium sulphate.

Mr. Clifford Richardson, in a paper on the chemistry of roller-milling of wheat, stated that the dark colour of north-western hard winter wheat could be overcome by using steel rollers run at different speeds.

Prof. Atwater has examined the nutritive value of different fish. He finds flounder to be the least value, and salmon the highest, and in invertebrates the oyster takes the lowest place as a food-stuff.

A lengthened discussion took place on the subject of valence in chemistry. Prof. Clarke remarked that it was especially useful in organic chemistry in explaining isomerism and in synthesis. It was also used in mineralogy; and he mentioned as examples of isomerism the three minerals kyanite, andalusite, and fibrolite, giving the structural formula for each. He then took up the questions of variable valence, invariable valence, and maximum valence as points that might be discussed. He remarked, further, that valence was an attempt to explain the arrangement of the atoms in a molecule, and spoke of the drawback of being obliged to represent them on a plane surface, space of three dimensions being much nearer the true state of affairs.

Prof. B. Silliman remarked that the last statement of Prof. Clarke was the key to the whole difficulty about valence. A plane surface is insufficient to explain the facts. He testified to the great utility of valence, and spoke of the chaotic condition of organic chemistry before this question of valence was appreciated. It was a working hypothesis, a scaffold without a building, but not the building. Hypothesis is not always the truth.

Prof. W. Ramsay said that the difficulties about valence could be traced to Lavoisier, who worked upon stable compounds, as oxides, chlorides. He also thought that a study of the heat of formation of many compounds would be a key to the valence of the elements; and said that the difficulties of conceiving of the motions of the atoms was well illustrated in Sir William Thomson's effort to explain them in complicated vortex evolutions.

Mr. A. H. Allen called attention to the failure of chemists to recognise the value of the work of John Newlands, in the periodic classification of the elements usually ascribed to Mendeléeff.

Prof. Greene remarked that it was best to consider the cause of valence.

Prof. Ira Remsen testified to the utility of valence. He remarked that there were two ways of teaching: one by giving all the principal theories first, and the other giving the facts and then the theories—which latter he considered the best method. He had come to the conclusion that valence should never be mentioned until all the important properties of a compound are known. In regard to its value to young students, he thought its use was dangerous until they fully understood its meaning. He believed that the value of valence had been magnified, and that it was better to study the reactions of compounds, and the methods for their synthesis, and the manner of breaking up.

Mr. A. H. Allen said that many formulæ that showed the structure of compounds according to the valence of the elements do not give any idea of the true constitution of these compounds as ascertained from a knowledge of their properties. He gave, as examples of his meaning, potassic dichromate and fuming sulphuric acid.

Prof. Dewar, of Cambridge, England, maintained that the graphical method and structural formulæ were most useful, but they are often presented in a way that shows an incomplete knowledge of the ideas of the person who devised the formula. He remarked that the text-books contained too many pictures of graphical formulæ, and that he considered it better to follow the historical method for developing theory.

Prof. Atwater thought that some idea of valence should be given at the beginning, as it assisted the student's memory.

Prof. W. Ramsay said that he was satisfied of the utility of making the student perform experiments that brought out facts to illustrate the theory of valence, so that he could thus understand its meaning from his own work.

Prof. Caldwell said that he could not get along with students in chemical analysis who had not obtained some idea of the theory of valence.

Prof. Remsen thought that the theory of valence might be some good as an assistance to the memory; but such assistance was of doubtful value, and too empirical.

Prof. J. W. Langley, Vice-President, said that valence, or chemism, may be a force emanating from the atom, or it may be a force outside the atom; it is static, or dynamic, and a knowledge of it was more a physical than a chemical problem. From the educational view he thought it better to use the theory of valence in connection with the history of the theories concerning atoms and molecules. As a further step, the language and figures of magnetism might be used.

Prof. Stewart described a process of making leather by treating hides with sulphurous acid under pressure.

Prof. Atwater has grown pease in washed sea sand, and found them to gain from 35 to 50 per cent. more nitrogen than they contained originally, and refers this increase to nitrogen directly absorbed from the air.

Dr. Springer, in a paper on fermentation, showed that a ferment exists in the stems of tobacco plants which decomposes nitrates and forms butyric acid from sugar solutions.

Prof. Dewar spoke of the density of solid carbonic acid, which he finds to be 1·58 to 1·60.

Other short communications were made by Prof. Munroe on deliquescence; on human milk, by Prof. Leeds; on gas analysis, by Dr. Elliott; and on fish oils, by Mr. Allen.

The most interesting discussion was on educational methods in laboratories and chemical lectures, by Prof. Remsen, who remarked that in Germany the student does not go into the laboratory until he understands reactions, while in England and the United States he is placed there at the beginning of the course. Prof. Remsen follows an order of instruction in which the student becomes first acquainted with apparatus and methods of manipulation. He next makes gases, and repeats lecture experiments. He then experiments on oxidation and reduction. Next follows the quantitative analysis of air. Then come alkalimetry and acidimetry, with success. This practical work and the lectures occur simultaneously, and by the time the lecturer has reached the metallic elements, the students are ready to take up test-tube reactions with profit. During the first year the student should only just begin analysis. After the general properties of the metals are known, let the student devise methods of separation. The course of instruction in our colleges Prof. Remsen regards as too short and superficial. Lecture-experiments should never be made for show. Æsthetics and chemistry are entirely distinct.

Prof. Atwater said that chemistry is taught now, as a rule, after the student has acquired the methods of the classics and has never been taught to observe facts. Chemists must show that their science will give what is called "liberal culture," or it will not find a place in our educational institutions. Present methods are not doing this, as they fail to make the student think for himself.

In the Section of Geology and Geography no paper was greeted with more interest or closer attention than that by Prof. J. E. Hilgard, Director of the U.S. Coast Survey, on the relative level of the Gulf of Mexico and the Atlantic Ocean, with remarks on the Gulf Stream and deep-sea temperatures. Its two most essential points are:—(1) The discovery by a most careful series of levels, run from Sandy Hook and the mouth of the Mississippi River to St. Louis, that the Atlantic Ocean at the former point is 40 inches lower than the Gulf of Mexico at the latter point; and (2) that ocean-water at all depths exceeding 1000 fathoms possesses a temperature of nearly 35° F., because this is the temperature consistent with its greatest density. Should the water become either cooler or warmer, it must expand; which it cannot do on account of the superincumbent pressure.

Prof Henry S. Williams, of Cornell University, in a paper on the influence of geographical and physical conditions in modifying fossil faunas, introduced the exceedingly important subject of the extent to which palæontological evidence is to be regarded as an absolute guide in correlating strata in different regions. Prof. Williams explained a series of sections, principally in Chemung and Catskill rocks, taken from a number of localities across New York State, and adduced from them abundance of proof that faunas in Devonian times, as at present, changed not only geologically in sequence of time, but also geographically according to the areas of their distribution. The influences which brought about a change in the character of the sediment deposited also manifested themselves in altering the forms of the organisms inhabiting these sediments.

Prof. Alexis Julien of New York communicated the results of a very extended study of the *Eozoon canadense* from nearly all the localities where it has thus far been found, adding other localities of his own discovery. The result of his investigations led him to decide in favour of the inorganic nature of the so-called fossil, although his ideas in regard to the mode of its formation differ considerably from any heretofore advanced. He noticed as universal in all localities, that the calcium and magnesium carbonates were very unequally distributed in the Eozoonal limestones, and that there was a large development of pyroxene where the dolomite was least abundant. He moreover observed the constant tendency on the part of pyroxene to be arranged in layers alternating with either calcite or apatite, as well as abundant evidence that pyroxene passed by hydration into serpentine, a process which could be seen in every stage at any of the localities visited. From these data it was assumed that siliceous waters, permeating limestones originally evenly dolomitic, would cause the local development of pyroxene by the change of the magnesium carbonate into the corresponding silicate. Were it the case, as so often occurs, that this pyroxene was developed in layers, its subsequent alteration to serpentine or loganite would readily account for all the appearances exhibited by the Eozoon, without the necessity of appealing to organic agencies.

A large number of papers (forty-three in all) were presented before the Section of Biology; but we regret that in our limited space we can give merely the briefest outlines. The first we may mention was a paper by Mr. D. C. Beyer, on the influence of oxygenated and unoxygenated blood, as well as of blood in various degrees of dilution, on the heart of the frog and terrapin. The paper aimed to prove that it is not concentrated mammalian blood which produces the greatest amount of work either in the heart of the frog or that of the terrapin, but that a certain degree of dilution is necessary.

Dr. C. S. Minot read a paper on biological problems. The author opposed the trinomial system, and considered the present mode of determining species entirely unscientific, and thought that the species should be based on a statistical study of all the variations that are known to occur. Individuals are not always homologous. The only fixed units are (1) cells; (2) the whole series of generations of cells from a single ovum—a cell-cycle. An individual may be almost any fractional part of a cell-cycle. Roughly speaking, the higher the organism the fewer the number of individuals it comprises. The author considered the ovum to be homologous with the encysted protozoon, the radial zone being equivalent to the capsule or cyst of the protozoon, and the contents also homologous.

Prof. E. D. Cope in a paper on the phyllogeny of the Artiodactyle mammals derived from American fossils, considered the derivation of the selenodont dentition from the bunodont as established from a mechanical point of view. The oldest American Artiodactyl (Pantolestes) is bunodont. The modification proceeded as in other ruminants on the lines of the co-ossification of the bones of the legs and feet. The peculiar structure of the carpus in the Oreodontidæ shows them to be, without doubt, the ancestors of the Tragulina. The following table represents the present views of the author on the subject:—

Tritubercular bunodontia (Pantolestidæ).

Selenodontia. Quadritubercular bunodontia.

Hyopotamidæ. Oreodontidæ. Poëbrotheriidæ.

(?) Pecora. Tragulina. Tylopoda.

Mr. H. F. Osborne presented observations on the amphibian brain, containing results of microscopic study upon the frog, Menobranchus, Menopoma, and Amphiuma. His method of study was by making series of sections, in their different planes. The relative position of gray and white matter was the same as that found in the spinal cord of these and other vertebrates. The courses of the principal nerve-fibres in their course from the medulla forward to the hemispheres was described, showing the course of the transverse commissures, and pointing out a commissure in the roof of the third ventricle hitherto overlooked. This demonstrated that each brain-segment had its own dorsal commissure. The differences of the cerebellum in the Anura and Urodela were pointed out, and the resemblances of the latter to the mammalian brain were dwelt upon. The pia blood-vessels are all sent in upon the anterior face of the pituitary body. The pineal elements were shown to consist of certain very inconspicuous foldings of the epithelium of the roof of the third ventricle, which have been generally overlooked. These foldings represent what remains of the stalk of the pineal gland.

Mr. S. Garman's paper on Chlamydoselachus, the frilled shark, treated of the internal anatomy of this peculiar shark. The nearest forms are Notanidæ, Hexanchus, and Heptanchus. Hind and fore brain resemble that of fœtal sharks; the cartilage is soft: the lateral line is open as in fœtal sharks, and continued to the end of the tail. The pelvis is twice as long as broad: the nearest resemblance to this is seen in the fœtal Heptanchus. According to the author, the Chlamydoselachus may be a sub order of the Galei.

The next paper was by Prof. E. D. Cope, on the mammalian affinities of Saurians of the Permian epoch, and referred to the detection of mammalian resemblances between Thesomorphus and reptiles of the Permian epoch. Resemblances in the pelvic and scapular arch were pointed out. The quadrate bone was discussed, referring to the theory of Albrecht. The genus

Clepsydrops shows that it has the mammalian number of bones in its tarsus, and the resemblance was nearest to that found in *Platypus anatinus*.

Dr. C. H. Merriam read a paper on the hood of the hooded seal (*Cystophora cristata*), describing it as an inflatable proboscis overhanging the mouth, and extending posteriorly to a point behind the two eyes, lined with nasal mucous membrane, and divided longitudinally by two cartilages. It is not noticeable until the male has reached its fourth year.

In a paper on some points in the development of pelagic teleostean eggs, Mr. G. Brook, Jun., first considered non-pelagic eggs, instancing those of trout, in which the hypoblast originates as an involution of the lower layer upon itself, the space between the layers being quite distinct. In pelagic eggs the process is quite different. Sections of the eggs of *Trachinus vipara* at this stage show that the parablast of Klein, the intermediate layer of American authors, is made up of a large number of free cells, and nuclei are absorbed from the yolk, which contribute to a very great extent to build up the hypoblast. In this case there is no true invagination. In *Motella mustela* the origin of the hypoblast is similar to that of Trachinus; but the resulting cells, instead of being quite similar to the original ones, as usual in teleostean eggs, are very much larger, and hexagonal, so that they cannot be derived directly from the lower layer of cells. The author sustained the views of Ryder as regards the segmentation cavity in pelagic eggs. He also holds that there is no circulation in pelagic embryos before hatching.

Mr. G. Macloskie, in a paper on the dynamics of the insect's test, commenced with a general description of the chitinous skeleton with its in- and out-growths, &c. The tracheæ have spinal crenulations, which have been hitherto misunderstood and supposed to be threads; these tracheæ transmit gases directly to the tissues, and the blood is not used for this purpose. The tracheæ are not directly controlled by muscles, their action depending on the successive production of a partial vacuum, and condensation of air around them.

Prof. A. Hyatt read a paper on the larval theory of the origin of tissue, stating that the building-up of the tissues of the Metazoa is due to a quick and rapid division of cells. Minot's theory that the origin of the sexes is due to the difference in cell elements was supported. The author considered the Planula a more primitive form than the Gastrula. In another paper Prof. Hyatt presented objections to some commonly-accepted views of heredity, asserting that heredity has no need of the gemmule hypothesis or pangenesis, but that it can be equally well understood upon the supposition that the nuclei of cells are the immediate agents of the transmission of characteristics. The author presented the case of a man in Maine, who resembled his mother on one side of his body and his father on the other side, as an illustration of his theory, and he contested the position of Prof. Brooks as regards heredity. In a paper on the structure and affinities of Beatricea, the same author stated that this fossil has had many positions assigned to it in almost all the groups of the Invertebrata, though he himself now thought it a Foraminifer. Thin sections were examined, the structure being found to consist of cells joined by a stolon.

Dr. C. S. Minot presented a paper on the skin of insects. The skin consists of three layers—externally the cuticula, overlying an epithelium, which lies in turn on a sheet of connective tissue; the epithelium is homologous with the epithelium of other animals, and should be so called instead of hypodermis; and dermis, which should be applied to the connective tissue, as it is the homologue of that of vertebrates. The cuticle of caterpillars has not yet been fully described: it consists of two layers, a thick one and a thin one.

In a communication on the development of Limulus, Mr. J. S. Kingsley stated that the account begins after the formation of the blastoderm. At this time there is a single layer of cells surrounding the yolk, in which are scattered nuclei. The mesoblast arises as a single sheet on the ventral surface. Its cells come largely from the blastoderm, but some arise from the yolk nuclei. The mesoblast soon forms two longitudinal layers, one on each side in the neighbourhood of the limbs. The cœlom is formed by a splitting of the mesoblast, and at first consists of a series of metameric cavities extending into the limbs. The supra-œsophageal ganglion arises by an invagination of the epiblast. The heart arises as two tubes in the somatophore, which later unite. The mesenteron does not appear until after hatching. The amnion of Packard is the first larval cuticle, and bears no resemblance to the amnion of the tracheata. A second cuticle is formed and moulted before hatching. The eyes appear on the dorsal surface at the same time that the limbs appear on the ventral. In these characters Limulus agrees essentially with the Tracheata, and has nothing in common with Crustacea.

Prof. B. G. Wilder, in a paper entitled, "Do the cerebellum and oblongata represent two encephalic segments, or only one?" remarked that most writers had considered two segments to exist. The cephalad of these segments is held to include the cerebellum, together with the portion of the "brain-stem" immediately connected herewith and the latter part of the oblongata. The only writers that have admitted of a single segment caudal of the mesen are Balfour, A. M. Marshall, Owen, and Spitzka. The views of Spitzka were then discussed, concluding with the opinion that sufficient evidence to settle either side was insufficient, and that the question was still open.

Dr. J. A. Ryder presented a paper on the morphology and evolution of the tail of osseous fishes. The caudal fin of fishes is developed in the same way as the median or unpaired fins, from a median fin-fold. After the protocercal stage of the larva is passed, a lower caudal lobe grows out, which is probably the homologue of a second anal fin. The hypotheses which grow out of a consideration of the facts of the development of the tails of fishes are the following:—(1) Whenever heterocercality manifests itself, there is a more or less extensive degeneration of the caudal end of the chordal axis, which began to be somewhat manifest far back in the phylum in such forms as Holocephali, Dipnoi, and Chondropterygians. (2) With the outgrowth of the lower lobes (second anal) the energy of growth tended to push the tip of the chorda upward; the lobe itself arising, probably in consequence of the localisation of the energy of growth and the deposit of organic material at the point, according to the demands of use and effort. (3) Local use and effort, acting as constant stimuli of local growth, carried the heterocercal condition and its accompanying modification of degeneration and reduction still further, as is shown by a study of the homologous elements in the tails of fishes; while use and effort would also continue to augment heterocercality, until the inferior and superior lobes were of about the same length and area, when the morphological characters of the caudal fin would become approximately stable for any one species, as may be shown by measurements of a simple mechanical illustration, in which the interaction and composition of the faces which are brought into action are demonstrated. (4) The mechanical demonstration alluded to above, taken together with the fact that the primitive or ancestral form of the tail, which is typified by a temporary condition in fish larvæ, when the myocomata are rudimentary, but still symmetrical, amounts almost to a demonstration of the principles first laid down by Lamarck, then elaborated by Spencer, and more recently applied to special cases by the author and Prof. Cope.

In a communication on growth and death, Dr. C. S. Minot gave the results of 10,000 measurements of weight of growing guinea-pigs and other animals from birth to maturity. The rate of growth was found to steadily diminish from birth onward; so that the loss of power begins at once, and continues until death. The common views of death were discussed, and the current conceptions of animal individuality were attacked. The author then referred to the bearing of our present knowledge of senescence upon the theory of life, and the relation of life to a material substratum.

A paper on the osteology of Oreodon was read by Mr. W. B. Scott, in which this genus was said to belong to the Artiodactyla, although there are some strong resemblances to the Suidæ. The vertebræ are ruminant, markedly in the case of the axis. The thoracic vertebræ have long prominent spines, and small bodies slightly amphicœlus. The lumbars, probably five in number, are heavy, with short spines and broad flat transverse processes. The sacrum contains two vertebræ which touch the ileum. The tail is long and slender, and the legs proportionally long. There are a short head and short metapodials, giving the animal a wolf-like appearance. The radius and ulna are distinct. The carpus consists of eight bones, including the pisciform. There are short unanchylosed metacarpals. The ungual phalanges are long and pointed, as in Hyopotamus. A rudimentary pollex is present, this being the only Artiodactyl with one.

Mr. J. Struthers, in a paper on finger muscles in *Megaptera longimana*, and in other whales, records rudimentary flexor and extensor muscles in these animals, and shows that they are more or less used, as the muscular fibres are red and not degenerated.

Dr. G. M. Stemberg described his experimental research

relating to the etiology of tuberculosis. The author repeated the inoculation experiments of Koch, with similar results. The experiments of Formad to induce tuberculosis in rabbits by introducing into the cavity of the abdomen finely powdered inorganic material, have also been repeated with entirely negative results. The author held that Koch's bacillus was an essential factor in the etiology of tuberculosis.

Dr. C. E. Bessey, in a paper on the adventitious inflorescence of *Cuscuta glomerata*, stated that the examination of young plants shows that the inflorescence is developed from numerous crowded adventitious buds, and not by the repeated branching of axillary flowering branches as commonly stated.

In a paper on the hitherto unknown mode of oviposition in the Carabidæ, Prof. C. V. Riley records habits of *Chlænius impunctifrons*, traced from the eggs up. The eggs are laid singly, in cells made of mud or clay, on the under surface of leaves.

Mrs. A. B. Blackwell read a paper on the comparative longevity of the sexes. The study was exhaustive, and made on statistics from all parts of the world; and the greater longevity of woman over man was established. In old countries the females preponderate, while males lead in newly settled ones. Up to eighteen years the males are in excess of the females: later the females predominate in numbers.

THE PRIME MERIDIAN CONFERENCE

THE Prime Meridian Conference at Washington on Monday adopted the Greenwich line as the universal prime meridian. Only one vote—that of St. Domingo—was given against its adoption; but the representatives of France and Brazil declined to vote.

The following details of the session are from the *Times* Correspondent:—

To the American resolution for adopting the Greenwich line, Mr. Fleming (Canada) moved an amendment to the effect that the Conference should adopt the 180th degree of longitude east from Greenwich as the prime meridian; but the other British delegates opposing the proposition it was lost. Señor Valera, the Spanish Minister, said that he had been instructed by his Government, in voting for the meridian of Greenwich, to say that it hoped the metric system of weights and measures would be adopted by England, the United States, and the other nationalities there represented, as recommended by the Conference at Rome. Gen. Strachey (Great Britain) said that he was authorised to state that his country had asked to be allowed to join the Metrical Convention, and that the metric system was already recognised by the laws of Great Britain, and was in use for scientific purposes. He could not, however, say that it would be adopted in any circumstances as a popular system of weights and measures throughout England. M. Lefaivre (France) said the Greenwich was not a scientific meridian, and that it implied no progress in any science, but was merely a commercial standard. Since, therefore, nothing would be gained to science by adopting Greenwich, France could not make a sacrifice of her own meridian, and incur the vast expense consequent upon the adoption of a new one, because she would thereby gain no advantage whatever. Sir William Thomson, who was present as a guest, by the invitation of the Conference, spoke in favour of the choice of Greenwich. He said that it was purely a matter of convenience, and that Greenwich answered the world's convenience better than any other standard meridian. Sir Frederick Evans (Great Britain) presented a statement showing that the shipping tonnage controlled by the Greenwich standard of longitude was about 14,000,000 tons, and that controlled by the Paris one only 1,735,000 tons. From the statement of chart sales, &c., to nations outside England, he showed how largely the Greenwich measure was used.

The resolution recommending the choice of Greenwich was then adopted, the ayes being 21, and there being but one nay—San Domingo. France and Brazil abstained from voting.

Mr. Rutherford (United States) moved that from the Greenwich meridian the longitude be counted in two directions, up to 180°, the east longitude being "plus," and the west "minus." The Russian Minister advocated this proposal, but Count Lowenhaupt (Sweden) moved the adoption of the fourth resolution of the Roman Conference for counting longitude continuously through the whole 360°. Herr von Alvensleben (Germany) said that this was a matter of detail, and therefore he should not vote upon it. The British delegates agreed with the German Minister that this was a matter of detail, and held that it would not make any difference which method was adopted. Señor Juan Pastorian (Spain) stated that he favoured the plan of counting longitude westward continuously round the world.

The discussion was here adjourned.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The beginning of Michaelmas Term shows that the University and Colleges have not been idle in erecting new buildings for the accommodation of students. The new buildings of Magdalen—to be called the Waynflete Buildings—are ready for occupation, and will be used this term. No one can deny that the most beautiful of Oxford Colleges has added a new ornament to the city in the Waynflete Buildings. The new buildings of Trinity College are rapidly approaching completion. Stretching back from quaint old Kettle Hall in Broad Street, they extend to near the beginning of the Lime Walk in the College Garden. The open space in front of the College—known as Trinity Green—will now be bounded on the east by these new buildings. The Green will thus become one of the largest "quads" in Oxford. On the north side of the University Museum the new Physiological Laboratory is rising. Its situation is one of the pleasantest in Oxford. That Prof. Burdon-Sanderson is attracting pupils to physiology is a patent fact in Oxford, and one that will be received outside that city with the strongest feeling of satisfaction.

Since last Term we have to deplore the loss of Mark Pattison, Rector of Lincoln College. Mr. Merry, Public Orator in the University, and Fellow and Tutor of the College, has been elected his successor.

The following scheme of lectures and classes has been agreed on by the Board of the Natural Science Faculty:—

In the Department of Physics Prof. Clifton will lecture on the Galvanometer and Methods of Measuring Electric Currents, and on Thermo-Electricity. Prof. Price will lecture on Optics, Physical and Geometrical. Prof. Clifton and Mr. Walker give instruction in Practical Physics in the Clarendon Laboratory. Mr. Walker will give a course on Questions incidental to the Practical Study of Mechanics and Heat. Mr. Baynes will give a course of lectures at Christ Church on Thermodynamics, and form a class for practical instruction in Magnetic and Electrical Measurements. Mr. Dixon will give a course of experimental lectures, on Elementary Heat and Light, at Balliol College. Prof. Pritchard will lecture on Spherical Astronomy, and form a class for practical work in the University Observatory.

In the Department of Chemistry Prof. Odling will give a course of lectures on 3-carbon and 4-carbon compounds. Mr. Fisher will lecture on Inorganic, and Dr. Watts on Organic, Chemistry. At Christ Church Mr. Vernon Harcourt will form a class for Volumetric Analysis. Practical instruction in Chemistry is given daily in the Museum Laboratory, and in the Chemical Laboratories at Christ Church and Balliol College. Prof. Gilbert will complete his course on the Constitution of Plants, and will then lecture on the Effects of Manures, Exhaustion and Variations of Season on the Amounts of Produce and on the Composition of Wheat.

In the Morphological Department Prof. Moseley will begin his course of Comparative Anatomy; each lecture will be followed by special demonstrations on the subject of the lecture. Dr. Hickson gives a course on the Morphology of the Vertebrata, each lecture to be followed by special demonstrations. Mr. Barclay Thompson lectures on the Anatomy of the Mammalia; Mr. Jackson on the Fundamental Principles of Comparative Embryology; Mr. Poulton on the Distribution of Animals; Mr. Morgan on Odontography and on Human Osteology. Prof. Westwood will lecture on the Insect Skeleton.

In the Department of Physiology Prof. Burdon-Sanderson will lecture on the Physiology of Circulation and Respiration. Practical instruction will be given in the Laboratory by the Professor, Dr. Dixie, and Dr. Gotch.

Prof. Bayley Balfour will give a course of lectures in the Botanic Garden, on the General Morphology of Plants.

Prof. Prestwich will lecture at the Museum on the Principles and Elements of Geology. Dr. Tylor will lecture on the Intellectual Development of Mankind.

During the course of the present Michaelmas Term, Scholarships will be awarded in Natural Science at the following Colleges:—At Balliol College, without limitation of age; at

Christ Church, limited to persons under nineteen; at Magdalen College, limited to persons under nineteen years on July 2, 1885.

Mr. J. N. Dobie has been elected to a Natural Science Scholarship at Exeter College in Biology and Chemistry.

CAMBRIDGE.—Mr. G. F. Harmer, B.A., of King's College, has been appointed Demonstrator of Comparative Anatomy. Mr. Harmer was placed in the first class of the Natural Sciences Tripos in 1883, being distinguished in Zoology and Comparative Anatomy.

An examination for Entrance and Foundation Scholarships will be held at Gonville and Caius College, beginning on January 9 next. Six Entrance Scholarships, varying in value from 40*l.* to 80*l.*, may be awarded. The successful candidates must come into residence in October 1885. They may be awarded for Classics, Mathematics, or Natural Science, separately or combined. They are tenable for a year, when the holder will be eligible for a Foundation Scholarship. The scholarships may be increased or diminished each year, according to the scholar's performances in the College or University Examinations. Those who distinguish themselves in the Triposes may have their scholarships prolonged after their degree. A successful candidate, who after the examination enters for competition at another College, forfeits *ipso facto* any scholarship for which he may have been recommended. Candidates must be under nineteen years of age on the first day of examination. Undergraduates of the College may at the same examination compete for scholarships, in which case there is no restriction of age. Candidates in Natural Science will be examined in Physics, Chemistry, Biology, and Animal Physiology, and will be expected to show proficiency in at least two of these subjects, of which chemistry must be one. The Rev. A. W. W. Steel, Senior Tutor, will furnish fuller particulars.

Lectures and Demonstrations on Physics and Chemistry in Michaelmas Term: Prof. Stokes, short course on Double Refraction and Polarisation; Mr. Atkinson, Heat and Hydrostatics; Mr. Glazebrook, Electricity (el.), also Advanced Physics; Mr. Shaw, Physics, Elementary and Advanced Mr. Hart, Mechanics and Heat (1st M.B.); Electricity (Nat. Sci. Tripos, Part 1); Practical Physics, Demonstrations and Practical Work at Cavendish Laboratory.

Chemistry: Prof. Liveing, General Course; Prof. Dewar, Dissociation and Thermal Chemistry; Mr. Main, Elementary Organic Chemistry; Mr. Pattison Muir, General Principles, and Elementary Chemistry, especially Metals; Mr. Heycock, General Principles (non-metals).

Demonstrations in Spectroscopic Analysis, Prof. Liveing; Special Demonstrations for Medical Students, Mr. Sell and Mr. Fenton; also Special Demonstrations for Nat. Sci. Tripos, Part 1; Mr. Robinson, Demonstrations in Analysis of Food and Water; Practical Work at the University, St. John's, Caius, and Sidney College Laboratories.

Prof. Lewis, Mineralogy and Crystallography; Demonstrations on Minerals, by Mr. Solby.

Prof. Stuart, Mechanism and Applied Mechanics; Mr. Lyon, Rigid Dynamics. The Mechanical Workshops are open from 8 to 1 and 2 to 6 daily.

Geology: Prof. Hughes, Economic Geology and Geological Surveying; Tides, Mr. E. Hill; Stratigraphy, Dr. R. D. Roberts; Palæontology, Echinoidea, Mr. T. Roberts; Constituents of Rocks, Mr. A. Harker. Field Lectures will be specially announced.

Botany, Elementary, with Practical Work, Dr. Vines; Physiology of Plants, Advanced, Dr. Vines.

Zoology and Comparative Anatomy: Prof. Newton, Evolution in the Animal Kingdom; Elementary Morphology (Invertebrata, Mr. Sedgwick; Advanced Invertebrata, Mr. Harmer; Mammalia, Living and Extinct, Osteology, Strickland Curator (Dr. Gadow).

Physiology, Elementary Course, with Practical Work, Prof. Foster; Chemical Physiology, Advanced, Mr. Lea; Advanced Course of Physiology and Histology, Mr. Langley; Preparation for 2nd M.B., Mr. Hill.

Human Anatomy, Muscular System, Prof. Macalister; also Demonstrations of Visceral Anatomy; General Pathology, Prof. Roy; also Practical Class in Morbid Histology.

Advanced Mathematical Lectures: Prof. Stokes, Optics; Prof. Cayley, Recent Developments in Analysis and Geometry; Prof. Darwin, Theoretical Astronomy; Mr. Forsyth, Higher Algebra, Binary Forms; Mr. Hobson, Higher Dynamics; Mr. Glazebrook, Higher Geometrical Optics; Mr. J. J. Thomson, Electrostatics; Mr. Macaulay, Thermodynamics; Dr. Besant, Theory of Equations, Differential and Integral Calculus; Mr. Lock, Fourier's Series, and Vibrations of Strings and Bars; Mr. Stearn, Hydrodynamics; Mr. Temperley, Laplace's Functions; Mr. Webb, Theory of Attractions and Elasticity, if a sufficient number apply.

THE formal inauguration of the University College of North Wales, Bangor, has been fixed for the 18th inst., and it is expected that the Duke of Westminster, the Earl of Powis, Lord Aberdare, Lord Penrhyn, Mr. Mundella, and other gentlemen, will take part in the proceedings. The fitting up of the new laboratories and lecture theatres for the chemical and physical departments is being rapidly pushed forward, and the buildings include a very complete suite of rooms for the use of each department. An excellent equipment of scientific apparatus has been secured for all branches of chemistry and physics. Mr. George Macgowan, F.R.S.E., formerly of Prof. Fresenius's Laboratory, Wiesbaden, and now of Prof. Kolbe's Laboratory, Leipzig, has been appointed Demonstrator in Chemistry under Prof. Dobbie, and Mr. D. M. Lewis, M.A., Trinity College, Cambridge, Demonstrator in Physics under Prof. Gray.

SOCIETIES AND ACADEMIES

SYDNEY

Linnean Society of New South Wales, July 30.—Dr. James C. Cox, F.L.S., Vice-President, in the chair.—The following papers were read:—Revision of the Lamellibranchiata of New Zealand, by Capt. F. W. Hutton, F.G.S. This is a carefully revised list of all the Lamellibranchiate mollusks of New Zealand, with the corrected synonyms and localities of each species. A list is also given of the names of each genus which had been wrongly included by previous authorities in the New Zealand fauna.—List of some New South Wales Zoophytes identified by Dr. Kirchenpauer, by Baron Sir F. von Mueller, K.C.M.G., F.R.S., &c. The list contains the exact localities of six species of Hydroida and fifteen of Bryozoa collected by Miss Bate on the south-east coast, and Miss Hodgkinson at the Richmond River. They were all detached from sea-weeds, and identified by Dr. Kirchenpauer, Burgomeister of Hamburg.—New Fishes in the Queensland Museum, part iii., by Charles W. De Vis, M.A. Mr. De Vis in this paper goes through the families *Berycidæ*, *Sciænidæ*, *Carangidæ*, *Scombridæ*, *Trachinidæ*, and *Triglidæ*, describing in all twenty-three new species, mostly from the coasts of Northern Queensland.—Census of Australian snakes, with descriptions of two new species, by William Macleay, F.L.S. The two new species are named *Dipsas boydii* and *Diemenia atra*, both from the Herbert River District, Queensland. The census gives the names, references, and localities of 108 species of snakes, thirty-five of these being innocuous, and seventy-three venomous. The paper concludes with some remarks on the immunity from snake-bite enjoyed by Australia, as compared with India.—On a new species of kangaroo (*Dorcopsis chalmersii*) from the south-east end of New Guinea, by N. de Miklouho-Maclay. A young kangaroo obtained by N. de Miklouho-Maclay in New Guinea, in 1880, has proved to be (on account of the great size of the præmolars, the general shape of the skull, and the direction of the hair on the neck) a new species of Dorcopsis, which he describes as *Dorcopsis chalmersii*, Mcl. The specific name, *Chalmersii*, is given in honour of the well-known and distinguished missionary of the south coast of New Guinea. The paper contains a full description of the animal and its dentition.—On a complete debouchement of the sulcus Rolando into the fissura Sylvii in some brains of Australian aboriginals, by N. de Miklouho-Maclay. A complete junction of the sulcus Rolando with the fissura Sylvii, which is very rare in brains of our race (a single case only having been described by Prof. Turner), has been found by the author in two out of four brains of Australian aboriginals. The junctions of the sulcus Rolando with other sulci are, according to Dr. Maclay, also not uncommon in brains of men of dark races, and occur more frequently than in the brains of men of the white race.—The Australian Hydromedusæ, part v. (conclusion), by R. von Lendenfeld, Ph.D. In this paper the monograph on the Australian Hydromedusæ is brought to a close. All known Australian species are enumerated, with the necessary references, and thirty new species discovered and described by the author are added. The total number of species

is 231. The most interesting of the new species are illustrated. The classificatory system established by the author is used.—Muscular tissue of Hydroid Polyps, by R. von Lendenfeld, Ph.D. A Hyroid Polyp discovered by the author in Port Phillip possesses a singular apparatus for escaping its enemies. This animal was investigated by Dr. R. von Lendenfeld, and a remarkable muscular structure was discovered. The histological structure of this is described, and some general conclusions drawn from the observations on muscular tissue, by O. and R. Hertwig, Claus, and the author.—Notes on the fibres of certain Australian Hircinidæ, by R. von Lendenfeld, Ph.D. The author discusses the origin of the "filaments," and describes some new and interesting peculiarities of the Australian Hircinidæ.—On the Myrtaceæ of Australia, by the Rev. W. Woolls, Ph.D., F.L.S. In this paper the author gives tabular statements of the distribution of this large order throughout the globe, but with special reference to its development in Australia. From an examination of these tables, as well as from other considerations, it is clear that West Australia must be regarded as the metropolis of the essentially Australian flora, the plants of the eastern portion of the continent bearing evident relation to Asiatic and Oceanic forms, while those of the west find their nearest, though still very distant, kindred in the yet more distant continent of South Africa.—On marine Annelids of the order Serpulea: observations on their anatomy, with descriptions of the Australian species, by William A. Haswell, M.A., B.Sc. The points treated of are the pseudohæmal system, the segmental organs, the tubiparous glands, budding and hermaphroditism, and the characteristics of the Australian representatives of the order. The arrangement of the vessels in several of the genera is described. Segmental organs of a simple type are shown to exist in addition to tubiparous glands which had been previously regarded as representing the segmental sacs of other *Polychæta*. Details are given of the structure of the tubiparous glands in a variety of genera.—On a new Crustacean found inhabiting the tubes of *Vermilia*, by William A. Haswell, M.A., B.Sc. In the tube of a Port Jackson *Serpulid* the author found several specimens of a remarkable Isopod, each with a brood of young. It proved to be a form differing in various points from any of the known families, but most nearly related to the Anthuridæ. The young were free in the cavity of the tube, sheltered, however, by fasciculi of hairs fringing the pereion of the parent. Like the "normal" Isopoda, and unlike the Anthuridæ, the embryos are flexed in the egg towards the dorsal side; there is a pair of jointed larval appendages connected with the second larval cuticle.—Note on *Pristiophorus cirratus*, by William A. Haswell, M.A., B.Sc. This remarkable genus of sharks was shown to be viviparous, and to possess a rudimentary shell thrown off in the uterus as in *Mustelus*, *Carcharias*, *Galeus*, and *Sphyrna*.

PARIS

Academy of Sciences, October 29.—M. Rolland, President, in the chair.—Note on the total eclipse of the moon on October 4, by M. Mouchez. Owing to its long duration, this eclipse offered a favourable opportunity for more exactly determining the diameter of the moon through the occultation of numerous small stars near the lunar disk. Although the weather was far from favourable, a sufficient number of observations were taken by MM. Périgaud and Bigourdan to advance the solution of this problem considerably. A large number of photographs were also taken by MM. Paul and Prosper Henry. The duration of the eclipse appeared to be rather less than the period theoretically determined.—Note on the experiments recently made at Turin and Lanzo to distribute the electric light to great distances, by M. Tresca. These experiments, carried out by Messrs. Gaulard and Gibbs in connection with the International Electrical Exhibition now being held at Turin, are stated to have been attended by a large degree of success. A Siemens' dynamo-electric machine of 30 horse-power generated an alternate current, which was simultaneously utilised by the Swan, Siemens, and Bernstein systems distributed over a circuit of twenty-four miles between the Exhibition, Lanzo, and intermediate stations.—Note on the nitrates present in plants at the various periods of their vegetable development, by MM. Berthelot and André.—On the explicit solution of Hamilton's quadratic equation in quaternions or in matrices of the second order, by Prof. Sylvester.—A fresh communication on a method of extracting the colouring matter from straw, by M. E. Cadoret, was referred to the previously appointed Commission; and a memoir by M. Goyet, on a project for the construction of a marine canal between the Atlantic and the Mediterranean was referred to M. de Lesseps for examination.—Results of the observation of the recent lunar eclipse made at the Paris Observatory (equatorial *coudé*), by M. Périgaud.—Note on the same eclipse as observed at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—Observation of the same eclipse, by M. Trépied.—Observations of Wolf's comet made at the Observatory of Algiers (0·50 m. telescope), by M. Rambaud.—Observations of the new comet, made on September 24, 25, and 26, by M. Perrotin. Under the spectroscope the nucleus yielded a continuous brilliant spectrum crossed by the three usual bands of comets, and by a fourth in the violet, like that observed some months ago in the spectrum of the Pons-Brooks comet.—Observations of the solar spots and faculæ during the third quarter of the present year, by M. Tacchini.—Remarks on the solar halos observed at Rome during the last four months (four illustrations), by M. P. Tacchini. This phenomenon, which has been constantly visible at Rome shortly before sunset since the first appearance of the after-glows in November 1883, is stated to resemble in every respect that already described elsewhere by M. Cornu.—Note on the action of water and of nitric acid on the basic acid of the bioxide of tellurium, by MM. Klein and J. Morel.—Note on the experimental study of infectious osteomyelitis, by M. A. Rodet.—On the elimination of phosphoric acid by the urine in cases of mental disorders and epilepsy, by M. A. Lailler.—Geological observations on the section of the Cordilleras traversing the Isthmus of Panama, by M. Ch. Mano. A careful survey of this region in connection with the works now in progress on the Interoceanic Canal has satisfied the author that the northern continuation of the Andes system following the double curve of the isthmus throughout its entire length, belongs to a far more recent geological epoch than that of the syenites and serpentines of Choco and Antioquia, whence they appear to branch off. They are also later than the diorites, volcanic and other porphyries of the Costa Rica coast range, which belong to the system of the Rocky Mountains, stretching thence northwards to the Polar Sea. The eruptive rocks of the isthmus seem to be contemporary with the volcanic formations of Auvergne, dating from the Quaternary or the dawn of the present epoch, and containing fossil human remains.

FIELD AND GARDEN CROPS

Diseases of Field and Garden Crops. By Worthington G. Smith, F.L.S. (London: Macmillan and Co., 1884.)

THE fact that a handbook of the diseases of crops has been written would not seem to other than botanists and agriculturists to be anything specially noteworthy. But in the British Empire, where plant economics is certainly better understood and its lessons more eagerly and thoroughly applied than in any other community, it is both true and surprising that no guide to the study of plant diseases and their prevention—at least none worthy of the name—has until now appeared. Nothing more admirable than the papers on vegetable pathology contributed by the Rev. Mr. Berkeley to the pages of the *Gardeners' Chronicle*, and the many writings of this and other authors scattered throughout our serial scientific literature, can, within their range and for their time, be shown elsewhere. But of recent years remarkable advances have been made, especially in Germany, in the study of the ætiology of plant diseases, and an excellent and comprehensive handbook was prepared a few years ago by Prof. Frank. Without doubt this author has gone as far as the state of science permitted him, but nevertheless a serious attempt to deal with vegetable pathology has yet to be made, and the attempt must be preceded by a great amount of laborious research. The activity shown in the investigation of parasitic diseases leaves little to be desired, but the many other ailments that the plant is subject to are but little regarded. That injuries are done by defective nutrition, by frost, and such like causes, is doubtless well recognised, but beyond this recognition there has not been very much inquiry into the matter. It is as if we were to be content with classifying the diseases of man into those due to the prevalence of east winds and the like.

While pathology is in this condition our therapeutical resources must continue scanty. Much may be hoped however from such researches in plant nutrition as those of Dr. Gilbert and Sir John Lawes. The means in our power of coping with the attacks of insects and of fungi are, it must be confessed, not very effective. There is doubtless something exhilarating in the wholesale destruction of insect pests by means of a judicious mixture of soapsuds and petroleum (applied on occasion by a fire-engine), and the heroic slaughter of the enemy may spur on the administrator to further and greater deeds, but except for very "local application" even this method will hardly lead to generally useful results. More—much more—is to be hoped from the encouragement of insectivorous birds, as recommended by entomologists. In fungal diseases our chief hope lies in "stamping out" either by means of the interception of a generation (where possible) on a comparatively worthless host, or by rigorous destruction of infected crops. It is true cases occur where timely amputation may save the remainder, and a method of cultivation (of potatoes) is under trial, the aim of which is to check the disease in each case at a certain stage of its progress—but the result will be seen. The introduction of new and "disease-resisting" races opens up also a means of evading fungal diseases.

Mr. Worthington Smith in the introductory chapter of his book laments that "there are no special teachers of vegetable pathology in this country, and the few men who have made the subject more or less a specialty, have not the time or opportunity for extensive or continued experiment and research." As one of those who have given much time and attention to this subject, Mr. Smith has here endeavoured to make up in some measure for this want by supplying us with a treatise on the diseases of crops, selecting such as are of the first economic importance, describing their phenomena in simple language, and considering the best means of preventing attack. With the exception of the attacks of Nematodes, he has confined himself to vegetable parasites, and of these he has supplied copious illustrations faithfully recording his views of the structure and the phases passed through by such organisms. The advice given throughout is cautious and to the point; the book is in very handy form, and within the reach of all in point of price. As such, then, it must be considered a decided gain to the farmer, the gardener, and the author's fellow-workers. Many of the last-named will regard with regret the fact that the author has not seen his way to accepting the proofs of so well-established a fact as the heterœcism of the *Uredineæ*. Mr. Smith devotes a chapter to the consideration of the subject, in which he attempts to combat the irrefragable evidence of the truth of this fact furnished us by experiment. Such objections, to give but one example, as that to the different periods occupied by the cultivation-experiments of different observers are not only of no account, but Mr. Smith must surely know from his own experience that the germination and further growth of spores as well as seeds vary exceedingly in different circumstances even under the same observer's hands. But it would be beyond the scope of this review were I to enter upon any defence of the existence of heterœcism in the Uredineæ. What is more particularly to be noticed in this section of the book is a theory of the hereditary nature of parasitic diseases. At p. 197 the author says:—

> "We have shown that plants invaded by *Puccinia* and *Æcidium* carry an hereditary disease by which they are saturated, and that the disease is capable of reaching the seeds and reappearing in the youngest seedlings. Now, if plants thus suffering from hereditary disease, and having the latent germs of disease in every part of their organisation, are experimented upon in an unnatural way, have spores of fungi placed near their organs of transpiration, whose germ-threads can pierce the epidermis or enter and choke the stomata and so reach their intercellular spaces, is it not likely that this inoculating process may start into activity the latent germs of disease?"

This is illustrated by the "instance of a person constitutionally subject to phthisis (consumption): give that person a cold and phthisis appears; but the same cold will give rise to rheumatic fever with a second constitution, and scrofula with a third, according to the tendency of the individuals to these disorders." Since Mr. Smith considers the heterœcism of the *Uredineæ* as not proven in spite of the nature and the amount of the evidence, one cannot help being profoundly astonished at the ease

with which he, even their own author, accepts such startling speculations concerning the hereditary nature of the parasitic diseases of plants.

In the matter of the potato disease, Mr. Smith gives a history of the whole subject, and a full description of the oospores, which he claims to be those of the *Phytophthora*. At p. 340 there is a sentence of some interest in view of the above-mentioned theory.

"It is quite possible, then, that just as every atom of a mycelial thread of this fungus (potato fungus) will continue its growth to a perfect form, so every atom of a broken-up flagellum—perfectly invisible to the eyes even when the highest powers of the microscope are used—may be capable of carrying the poison and at length reproducing the perfect form of the fungus in the potato plant."

Everything is possible, but some things are undoubtedly highly improbable, and chief among these are those which we have not the slightest grounds for supposing probable. Such is the case with this speculation since (to take the flagellum only) in the first place it is not by any means certain, as the author indeed points out in the same paragraph, that a flagellum breaks up at all, and in the second it is quite unwarrantable on any known basis of fact to suppose that its fragments are endowed with any reproductive function.

Apart from such speculations, I venture to think that Mr. Smith has rendered the study of vegetable parasites a signal service in the publication of this book. Its practical uses to the farmer and the gardener are apparent, and to the student of the subject the advantage is no less, even in those cases where the author differs from the great majority of his fellow-workers, since "the case for the opposition" is as well and as strongly stated as the materials permit. The book is of practical value in this country, and it is, moreover, one which no intelligent agriculturist can afford to dispense with in these times, when farming is engaged in a struggle of such severity at so many points. GEORGE MURRAY

OUR BOOK SHELF

How to Foretell the Weather with the Pocket Spectroscope. By F. W. Cory. (London: Chatto and Windus. 1884.)

IT is of little use putting any instrument, however simple it may look, into a student's hands, if he is not previously taught how to use it. This needful information is supplied by the handy little book now before us, showing what can be done with a direct-vision spectroscope only some 3½ inches long.

The book commences by describing two pocket spectroscopes now in use: the "rainband spectroscope," and a newer and somewhat larger instrument, "Grace's spectroscope," which, however, is still small enough for the pocket, being only 5½ inches long when closed, and which has the advantage of giving a larger spectrum. Here, however, there is a most important omission, for the adaptation of a lens to focus the image of a cloud or a part of the horizon on the slit is not referred to. Instruments thus armed are far better than those of the ordinary construction for meteorological purposes, and, as made by Hilger, they are not appreciably larger. We are next told how to use the spectroscope, and a map is given (Plate 1), showing the positions of some of the lines which the student should learn to recognise in the spectrum of the sun, in order to see at once if the rainband is present or not.

On another page we find the principal rainband itself (Plate 2), which is instructive as showing the student what to look for; but in the construction of this map a larger spectroscope, of two prisms, has been employed, so that if the student in looking for the rainband uses his pocket spectroscope, he will be somewhat disappointed. It would have been more complete if a drawing of the rainband, as seen with Grace's spectroscope, could have been given side by side with Plate 2, which shows so much of the detail.

The book concludes with letters, reprinted from the *Times*, from the Astronomer-Royal for Scotland and others, showing the value of the spectroscope for meteorological purposes.

We think no one can lay down this little volume without feeling this opinion confirmed, and that in the pocket spectroscope we possess an invaluable instrument with which to forecast the state of the weather. B.

Celestial Motion: A Handy Book of Astronomy. By W. T. Lynn. (London: Stanford, 1884.)

MR. LYNN'S long training at the Royal Observatory has eminently qualified him to write this little book. It is in no sense a school-book, but all the same it contains a most useful introduction to those parts of the science of astronomy of which it treats. These are the earth, sun, and moon; the planets arranged in three groups; comets, meteoroids, and the fixed stars. There is added a very painstaking and concise history of astronomical discovery, the only blot in which is an ineffective reference to spectrum analysis at the end.

The First Six Books of the Elements of Euclid, and Props. i.—xxi. of Book xi., and an Appendix on the Cylinder, Sphere, Cone, &c. With copious Annotations and numerous Exercises. By John Casey, LL.D., F.R.S. (Dublin: Hodges, Figgis, and Co., 1884.)

THIS is the second edition of a work which so accomplished a geometer as Prof. Henrici (vol. xxix. p. 453) has pronounced in these columns to be in many respects an "excellent" book. As the first edition contained 254 pages, and this one reaches 312 pages, it is manifest that the work has grown—and with its growth we find that it has acquired an accession of strength. We will indicate in what directions it has increased. First and foremost is the addition of the propositions of Euclid's Eleventh Book, which are generally read by junior students, and an appendix (well suited for candidates for the London Intermediate Examination) on the properties of the prism, pyramids, cylinder, sphere, and cone. There is also now given an explanation of the ratio of incommensurable quantities, and a still greater number, than in the first edition, of alternative proofs. Further, we can testify, by a careful perusal of the text, that the work has been "thoroughly revised as well as greatly enlarged." One feature we note, that whereas in the first edition the *syllabus* of the Association for the Improvement of Geometrical Teaching was often referred to by quotation, in this edition the name occurs but once or twice. There are reasons for most actions—we presume there are for this course of action.

We are glad to note that Dr. Casey makes frequent use of the term *right* line; the absence of the word "right" is liable to lead young boys astray: we should also prefer in one or two instances the term "circumference" (the line) to the term "circle."

Numerous easily rectified clerical mistakes occur, and we could wish that the author had uniformly written *AB* for a line drawn from *A* to *B* instead of apparently writing the letters haphazard. The terms *area* and *perimeter* are employed without definition; a work by Prof. Townsend (p. 142) is referred to without giving exact reference; and an examination question (p. 173) in-

volves an acquaintance with Gauss's discoveries in regular polygons without the information having been given to the student. The proofs of i. 9 and iii. 35 appear to us to admit of improvement, the first by the familiar addition of "on side remote," &c., and the latter might advantageously be curtailed. These are small faults in a work of such extent, and we instance them to show how little we find not to our liking in an admirable text-book. We notice that Dr. Casey has adopted the convenient terms "circum-circle," "circum-centre," &c., first introduced, we believe, by W. H. H. H. in these columns. He also calls a certain well-known locus by the name of "Simson's line," following the practice now usually adopted by geometers in this country, we do not know on what authority; that well-informed writer in the *history* of the subject, Mr. J. S. Mackay, states in his edition of Euclid, recently reviewed in these columns, that he had not met with the property in Simson's writings.

Prof. Henrici in his article on "The Axioms of Geometry" (NATURE, *l.c.*) does not approve of Dr. Casey's treatment of the Fifth Book (the Algebraic), and criticises adversely Hamilton's quaternion proof of Euclid i. 32, given by our author in an appendix (cf. also NATURE, vol. xxix. p. 573). Dr. Casey prints the article as in the first edition, and takes no notice of the criticisms we refer to. A very large and well-selected collection of exercises (upwards of 800 we think), with the addition (now) of numerous examination questions, complete a work every way worthy of the reputation of the great Irish geometer.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Sky-Glows

ON reading Prof. Herschel's letter in NATURE for October 2 (p. 536), in which he so vividly describes the sunset of Sept. 20, I was so forcibly reminded by its similarity, especially with regard to the "diverging beams," to one which I lately witnessed during an excursion to the White Mountains (New Hampshire), that I send you a short account of it. It occurred on the evening of September 9 while we were staying at Twin Mount House, at a short distance from which is an elevated wooden erection, commanding splendid views of the neighbourhood. We had been watching the shadows creeping over the hills, the evening light reflected on a bend in the river below, had seen the sun go down behind the soft gray outlines of Mount Agassiz, and revelled in the glorious tints, such as Prof. Herschel describes, when, on returning to the hotel and stepping out on the balcony to take a last look, we saw, from the point where the sun had lately disappeared and where the fiery glow still lingered, these remarkable "diverging rays," so distinct in their character and so sombre in their dark (though slightly greenish) shadow-like hue—there were not many of them—that I involuntarily exclaimed that I had never seen anything like them before, and that surely the climate must have something to do with their striking appearance and unusual definition. I may mention that the day-glow was also conspicuous at times on that continent, notably at Quebec on August 25 last.

Since writing the above, I find that your correspondent, Mr. J. E. Clarke (September 18, p. 488), also refers to dark bars at sunrise and sunset, and the radiating character of the latter.

Further Barton, Cirencester, October 17 E. BROWN

THAT Mr. Backhouse is right in thinking the day-glows were entirely fresh in November of last year, the following extract from my diary confirms. As ordinary meteorological phenomena are entered upon a daily chart, my note-book only refers to what is unusual. Those whom I called to notice the sky thought it quite strange. "1883, xi. 25.—SKY COLOURING at 2.45 to 3 p.m. of a pale rosy-pink tint to the blue, giving a greenish-gray cast to cirro-cumuli where it shone through. Formed circle round sun extending from about 10° to 25° or 30° away. Inside the 10° sky yellowish. Can this have anything to do with the green sun seen in India, and therefore with the Java eruptions? Have noticed once or twice of late unusual sunset-colouring *very* late. At 4.30 strange ruddy or bright red tint on brick houses in Bootham. At 5.30 the west ruddy, as from glare of fire; still signs visible of this up to six. Sunset at Greenwich at 3.58; therefore here at 3.38. Notice also various newspaper reports and also in NATURE of striking appearances after sunset, ascribed to auroras, &c." J. EDMUND CLARK

Bootham, York, October 19

Cole's Pits

IN reference to the subject of the "Cole's Pits," respecting which a notice from Mr. A. Irving appeared in NATURE for Oct. 9 (p. 560), I find that as early as 1784 these pits, or rather perhaps some of them, were investigated by the Hon. Danes Barrington. And a paper appears on the views entertained by him regarding them in *Archæologia*, vol. vii. p. 236, under the head of "An Account of Certain Remarkable Pits, or Caverns, in Berkshire." Although Mr. Barrington expresses some doubts as to his conclusions, he nevertheless leans to the opinion that they are the winter dwellings of a pre-Roman people, the entire series constituting perhaps an ancient British town. He estimates them at about 273 in number, and covering a space of about 14 acres. In depth they vary from 7 to 22 feet, and are 40 feet and upwards in diameter, the largest being not in all instances the deepest. They extend in regular series, and are placed rather closely to each other. They are referred to a period anterior to that of Stonehenge; and it is conjectured that if each pit contained five occupants the entire community would have numbered something like a population of 1400 souls. As suitable for the residence of uncivilised people stress is laid on the fact that the place is entirely of the dried sand on the rich vale of the White Horse. The dwellings are supposed to have been entered by climbing down a rude ladder or notched pole after the manner adopted by the natives of Kamchatka in reaching their underground habitations. It is remarkable as bearing on the theory that these pits are abandoned quarries, that no objects, such as pottery, indicative that they (the pits) were used as dwellings, were found by Mr. Barrington. There can be no doubt that the pits are simply the sites of shafts dug for the purpose of obtaining the underlying ironstone. Indeed, Mr. Godwin-Austen appears to have set the matter at rest many years ago; and although I am not able at the moment to state in what paper on the subject the opinion occurs, I am in possession of a note in which Mr. Godwin-Austen, with the keen perception of the skilled geologist, observes that although "the Faringdon tradition points this spot out as the site of the castle of King Cole, whose memory is preserved in a well-known fragment of popular poetry, geology can countenance no fictions except its own, and Cole's Pits are evidently the remains of the open workings for the ironstone underlying the mass of sand."

Reading, October 10 JOSEPH STEVENS

Circular Rainbow

THE circular rainbow mentioned by Mr. Marshall seems to be similar to what may be seen at the Niagara American Falls by persons who are fortunate enough to have taken the trip under a portion of that Fall at the right time. When coming out into the front of the Fall, if the sun be shining and in a favourable position, each observer is surrounded by a rainbow of which his eye is the centre, and which accompanies him while in front of the Fall like the halo of a saint of old, but larger.

Before railroad days, when travelling by coach from Bristol to Bridgwater, I once saw a complete circular rainbow resting on the vale below the Leigh Woods, just out of Bristol.

Barnstaple, October 20 W. SYMONS

P.S.—One morning, as the sun was rising over the Southern Atlantic, the sea being moderately rough, I saw each white crested wave drowned with the prismatic colours, causing a dancing play of glorious colour never to be forgotten.

THE NEW GEOLOGICAL MAP OF RUSSIA[1]

GEOLOGISTS will be glad to hear of the appearance of the first sheet of the "Geological Survey of Russia," published by the Geological Committee on the scale of 10 versts to an inch. It comprises nearly the whole of the Government of Yaroslav and the eastern parts of Tver, between 57° 0′ and 57° 42′ N. lat., and 43° 10′ to 47° 40′ E. long., corresponding thus to Sheet 56 of the General Staff Map of Russia. This region, which is watered by the Upper Volga, the Mologa, and the Sheksna, is an undulating plain, the highest points of which, close to Bejetsk, reach 700 feet above the sea-level, gently sloping east and west to a level of from 350 to 420 feet. It has been dealt with first on account of a series of geological explorations which have already been made within its limits. It was visited by Blasius, Murchison, Keyserling, and Barbot-de-Marny, and careful explorations have been undertaken during the last few years within the limits of the province of Yaroslav, under the direction of its Provincial Assembly and Statistical Committee, by MM. Schurovsky, Piktorsky, Eremeyeff, Dittmar, Kryloff, and Nikitin.

The map, which has been prepared by M. Nikitin, is very carefully printed, and will be the more welcome to European geologists as all important names and explanations are given in French, side by side with the Russian text. The colours and the explanatory letterpress are in conformity with the recommendations of the International Geological Congress. A quarto volume, in Russian, by M. Nikitin, with plates and drawings, accompanies the map, the whole being summed up in German at the end of the volume.

The first thing which strikes one on looking at the map is the very great space covered with the gray colour of the Quaternary deposits. A greenish patch of Jurassic rocks in the middle of the map, several patches of Trias on its borders, and a very small Carboniferous patch, altogether hardly cover one-third of the surface; the remainder representing the "Boulder Clay, which conceals deposits of unknown age." The thick sheet of Boulder Clay will be for a long time the stumbling-block of Russian geologists. Natural sections are found only on the banks of the greater rivers, while the valleys of the smaller ones, to their very bottom, are cut through Quaternary deposits. Even the two railways that cross the space covered by the map have been laid without excavations of any importance to the geologist; and no artificial excavations worthy of notice are to be found in the whole area.

As to the geological description which accompanies the map, it is full of interest. The Carboniferous deposits which are denuded over a very limited space in the north-west, belong to the Upper series, characterised by *Spirifer mosquensis*. They probably extend throughout the region in nearly horizontal strata gradually inclined towards the east; but they are concealed by the Variegated Marls which are the subject of so lively a controversy among Russian geologists, and which are considered by the author as belonging to the Trias, contrary to the opinion of the Kazan geologists, who consider them Permian. Although appearing on the surface only in isolated islands, these Marls probably also extend throughout the Yaroslav region; the salt-springs at least, which appear at many places, and which usually take their origin, in Russia, either in the Devonian or in the Variegated Marls, seeming to indicate a great extension of these deposits. The Jurassic formations appear now (as throughout Middle Russia) only as sporadic islands, which are remains of a widely-extended strata destroyed by denudation; the Jurassic sea, according to the author, extending at least as far north as the latitude of Tver. The Jurassic deposits, which have been, like the Variegated Marls, the subject of special monographs by M. Nikitin, are represented in the Yaroslav region; the lower ones by the Callovian and the Oxford Clay, the two chief subdivisions of the former being characterised respectively by *Cadoceras Milaschevici* and *Quenstedioceras Leachi*, and those of the latter by *Cardioceras cordatum* and *C. alternans*. The Upper Jurassic is represented by the "Volga Series," Lower and Upper, respectively characterised by *Perisphinctes virgatus*, *Oxynoticeras fulgens*, and *Olcostephanus subditus*. They are invariably covered with a sheet of sands (like the Jurassic of Central Russia), which seems to have been a littoral deposit accumulated during the retreat of the Jurassic sea.

A very interesting chapter is devoted to the Quaternary deposits of Yaroslav and Central Russia. The thick sheet of Boulder Clay which covers Central and North-West Russia, and contains erratics from Finland and Olonetz, as also from those regions which the erratics had to cross on their way from the north, has long been a puzzle to Russian geologists. Within the limits of the map, it appears with its usual characters, that is, those of a layer 8 to 10 m. thick, spread without interruption over the country—over the watersheds as well as the valleys—without any traces of stratification or even of striation by water: the thickest boulders and the finest particles appearing closely mixed together without bearing any traces of sorting by water-currents. As to the boulders, they are of all possible sizes, from a grain of quartz to masses 2 and 3 m. in diameter. While crystalline rocks and schists from Finland and Olonetz are prevalent, local boulders—Carboniferous and sometimes Jurassic—are also not absent, especially in the lower strata. The boulders have a tendency towards a disposition in ridges which run from north-west to south-east, crossing the rivers, or rising sometimes in the shape of moraines, or eskers of great size. A sheet of boulder-bearing sand, with traces of stratification, appears at many places beneath the Boulder Clay, which passes also in its upper parts into an unstratified sand with boulders.

Such being the character of these deposits, it is obvious that the theory fails which tries to explain them by floating ice, as does also Prof. Trautschold's theory of "Eluvium." The author accepts, therefore, the theory now generally adopted by geologists, and specially advocated for Germany by Berendt, Penck, and Bernhardi, and for Russia by P. Krapotkin, and considers the Russian Boulder Clay as an equivalent of the *Krosstenslera* of Sweden. Like the British Till, it is no doubt the bottom-moraine of the great ice-sheet which covered Northern Germany and Russia, without reaching the Ural Mountains, during the ice-period. This period succeeded to a relatively mild climate, when the plains of Moscow were covered with thick oak and maple forests, inhabited by the mammoth and the rhinoceros, which were compelled by the ice-sheet slowly advancing from the north-west to emigrate east and south. The Loess of Southern Russia, and the Loess-like deposits of the intermediate region, were probably contemporary with the glaciation of the north.

Another chapter is devoted to the formation of rivers in European Russia, and to the great processes of denudation in the later parts of the Quaternary period. This subject has been keenly discussed of late by Russian geologists. The author is to be congratulated on the scientific manner in which he has laid the basis for a discussion of the three important questions—as to the Variegated Marls, the Boulder Clay, and the more recent alluvial deposits—with which he has had to deal in this first fascicule of the Geological Survey of Russia.

EARTHQUAKES

THOSE observers who have undertaken the detailed study of a region severely injured by an earthquake are well acquainted with the difficulties that attend on

such a perilous and unthankful work as examining the ruins. The necessity is soon felt for some means of accurately registering the various characters of the earth's movement. The imperfect record of the features of an earthquake afforded by broken walls, fissured roofs, and overturned objects is dependent upon a variety of causes.

1. The earthquake consists of a series of movements that do not radiate from a mathematical point, or even from the focal cavity, with perfect uniformity.

2. The group of disturbances which constitute a shock (of variable duration) may not arise from the same point, as, for instance, in the rending of a fissure in an upward direction, the first impulses would be derived from a much lower point than the last.

3. The great variation in the physical qualities of the rocks traversed, dependent upon their composition, intimate structure, and mode of arrangement. Also we may here include the irregular conformation of the surface.

4. The want of homogeneity and of regularity in the structure of houses and walls, and also the presence of door and window openings.

5. The presence of old fissures in buildings, either the result of displacement, shrinkage, or former earthquakes.

Were it possible to construct absolutely perfect instruments for registering the complex movements of an earthquake, we should be able to exclude the two important causes of error coming under the heads (4) and (5), but the others can never be removed, unless that under head (3) might be so by a complete knowledge of the subterranean geology of a district in question—a far from easy matter.

After perusing the recent paper by Prof. J. A. Ewing on "Measuring Earthquakes" (NATURE, vol. xxx. pp. 149 and 174), one might despair of ever understanding the complex tracings the author obtained. A more careful consideration of the subject would seem to help us out of the difficulty to a considerable extent in so far as theoretical reasons will permit us, and it is not till suitable seismographs have been fairly tried in other districts than the unsuitable alluvial plain of Yeddo that we shall learn whether there is any practical use in instrumental observation of earthquake movements.

In an alluvial plain like that of Yeddo, reposing as it probably does on the irregular surface of different but more elastic rocks, from which are transmitted to it the vibrations, the condition is such that a number of waves would be reflected and refracted so as to meet each other at various angles interfering with each other and producing very complex results on any pendulum instrument.

I am personally neither acquainted with the geology of the region in question nor with the type of disturbances constituting its earthquakes, yet from descriptions of the latter one would feel inclined to regard them as the tail-end movements of powerful shocks far below the surface, conditions highly favourable to complexity from reflection and refraction. Besides, the incoherent alluvium, often water-logged, is subject to a remarkable disturbance when vibrations are communicated to it from without, as may experimentally be illustrated by spreading jelly, or, better, mud, over the irregular surface of a piece of wood and tapping with a hammer.

These remarks may at first sight appear beyond the question, but we must not leave the subject without further trial. Any one who has studied the injuries resulting from destructive earthquakes such as that of 1857, described in Mallet's classical memoir, or of those of 1881 and 1883 in Ischia, cannot but be struck with the regularity of the injuries when the observer carefully excludes the large number of modifying influences, as heterogeneity in structure of buildings or the surface configuration of the point in question.

The following instruments were suggested by the study of the two great Ischian earthquakes, and with suitable modifications might be made appropriate to study small or great shocks as the case might require. The use of a pendulum as the main part of the mechanism has many objections, which have often been pointed out, and I think that future investigations will strongly confirm such opinions. Nevertheless I have given examples where the pendulum may be used, or replaced by other methods employing the same type of registering apparatus (Fig. 1). *a* is a pendulum with preferably a pear-shaped bob of great weight, which has attached to its lowest point a strong plaited thread of dentist's silk, *e*, which passes through a perforated glass plate, *d*. The hole in the glass plate is smoothly drilled of the exact size of the silk thread, so as to allow it to run easily but no more; it has its lip smoothly rounded off so that a section of the edge (see *d'*) is semicircular. The glass plate is firmly gripped by the horizontal metal plate *c*, which is rigidly fixed to the supports *b*, which in their turn are embedded in a solid masonry or rock basement. The silk thread is connected by a light wire cage, *f*, to the cylinder *g*, which slides easily up and down the fixed triangular column *h*. The cylinder *g* is connected to the writing arm lever *i*, which

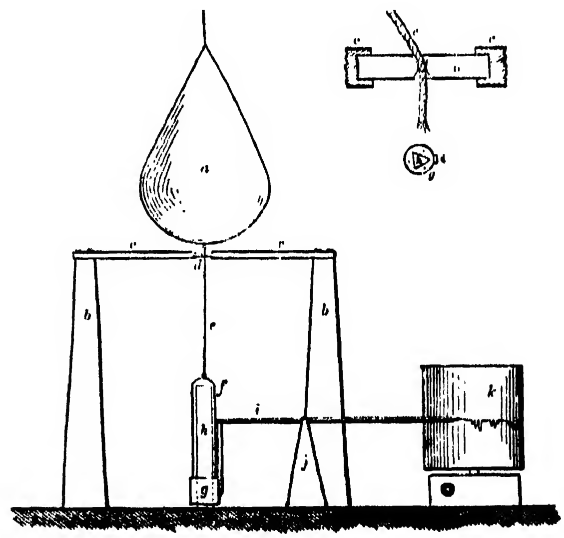

FIG. 1.—Pendulum apparatus to register amplitude of wave continuously.

may be short, and write directly on the recording drum *k*, being then a simple stylus, or, as in the figure, arranged to magnify the amplitude two or more times at choice.

When any earth-movements take place, the *relative* horizontal swings of the pendulum are converted into vertical movements of the silk thread, cylinder, and stylus, which on a time-ruled recording sheet will give accurate amplitude tracing minus the friction of the apparatus, which, if well constructed and the pendulum proportionally very heavy, may be excluded. By using a heavy pendulum with short suspension we may measure oscillations of short period, or, by using a long suspension and a delicate apparatus with greatly magnifying lever, this apparatus might be a useful tromometer, or measure of slow earth oscillations or tiltings (Fig. 2).

Three solidly-fixed cast-iron uprights, *a*, support a circular massive cast-iron plate, *b*, which has a conical aperture at its centre. Resting upon this is a circular sheet of plate-glass drilled at its centre in the same manner as the silk thread perforation in Fig. 1, as it serves a similar

purpose. This glass plane must be perfectly horizontal. A circular disk of lead, *g*, is inclosed between glass planes, *d*, and rests on three perfect spheres, *f*, which should be preferably of glass or ivory. Rigidly attached at its centre on the lower side is a conical spire, *m*, whose point reaches just the level of the glass plane *c*, and has fixed to it the silk thread *n*. From the centre of the upper side

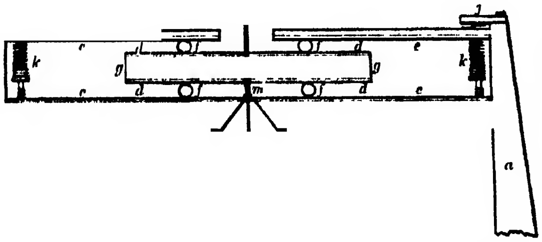

FIG. 2.—Ball and plane seismograph for indicating amplitude and azimuth in all phases of a shock.

projects the steel stylus *o*, bearing a fine platinum wire at its extremity, which may be used with the double azimuth circle of Fig. 3 in a direct manner in case of large earthquakes, or by a lever supported in gimbals, as also in Fig. 3. Another glass plane, *c*, with a large circular aperture at its centre for the free movement of the azimuth stylus *o*, has a wrought iron trellis work backing *h*. This reposes on the springs *k*, which are regulated by the

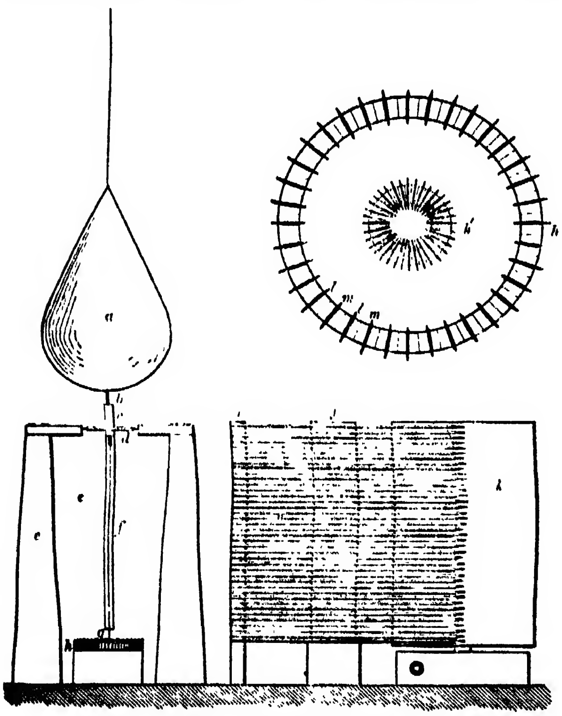

FIG. 3.—Azimuth register of wave path in all phases of an earthquake.

milled-head screws *l*, so that it is only pressing sufficiently on the upper balls *f* to keep them in place. The upper springs *i* are introduced to allow slight freedom of motion to prevent breakage of the plates in almost vertical shocks or from the expansion of the lead disk, balls, &c. The silk thread is connected to the registering apparatus in the same manner as in Fig. 1, the slight weight of which will tend to draw back the rolling lead disk to its central position, and so prevent it shuffling out of its place, and yet have almost no effect in modifying the register of the absolute wave amplitude.

In working over an earth-shaken district of small area, such as that of Ischia, an error of observation of azimuth of even a few degrees matters little in determining the exact position of the epicentre. But on the contrary, in large areas such as the Neapolitan earthquake of 1857, and to a far greater extent in widespread disturbances such as the great Lisbon catastrophe, an error of a few minutes of a degree is sufficient to produce great divergence in the orientation of the azimuth and a consequent incorrectness in the location of the epicentre. In most seismographs so far employed, especially those of Italy, no attempt has been made to divide the circle into eight divisions, so that an error of nearly 45° could occur.

Fig. 3 represents a separate apparatus, although it would probably in practice be found preferable to replace the pendulum by the rolling disk and balls as already mentioned when describing Fig. 2, except that the contact rings *h* would then be inverted. A pendulum, *a*, with a

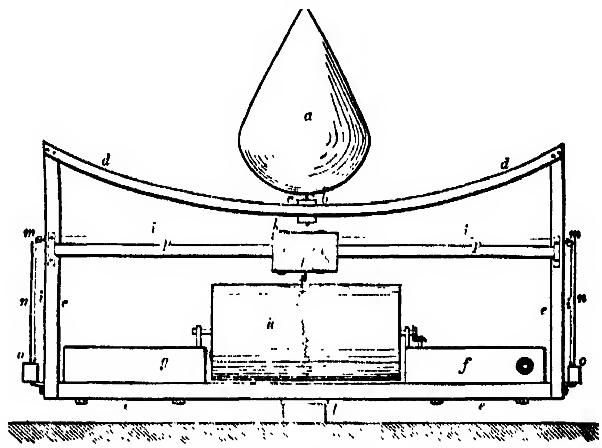

FIG. 4.—Horizontal component of wave-path register for strong and destructive earthquakes.

length of suspension suitable to circumstances of observation, carries a steel spring wire, *b*, which slides in the cylinder *c*, which, together with the light wire arm *f*, forms a universal lever moving about the fulcrum at *d*, which are gimbals. This lever should be so balanced that, if placed in a horizontal position, the part above *d* should counterpoise the part *f*. The lever carries a fine platinum wire, *g*, which, when at rest, is the centre of the two contact circles *h*, *h'*, *h''*. This part of the mechanism is in connection with one pole of a battery.

The contact circles *h* seen in detail, *h*, *h*, consist of a suitable number of brass segments, *l*, which have a V-shaped groove on their upper surface, and the edges, both inner and outer, are bevelled off. Each one is insulated from its fellow by the vulcanite plates *m*, which project a little on the inner, upper, and outer sides, and are sharpened to a knife edge.

The registering apparatus consist of a number of long soft-iron spring styles bolted to the column *i*, with their

points near the revolving register cylinder k. A pile of electro-magnets, j, each of which is in connection with the two corresponding segments of the two contact circles and the battery, when the current passes, draws one soft-iron spring style towards its poles, and brings the point in contact with the cylinder k. The pendulum might be made to act directly on the contact circles without the magnifying lever $c\,f$, if thought necessary, and the breadth of the outer circle might be greater and give a correspondingly longer dash so as to distinguish those derived from the two circles.

It will be seen that the most complex movements of the pendulum or rolling disk can be accurately registered, since four contacts will be marked in each semiphase of the oscillation of the pendulum, and a fifth point can be obtained by calculation from the instrument for registering amplitude, which, together with the position of rest, will give sufficient data to obtain the loops for each semiphase throughout the disturbance.

In large earthquakes where the wave-amplitude is very great, the rolling disk and balls would require to be of very great size, which in many cases it might be impracticable to carry into execution, although the results might be of great perfection in so doing. The present instrument (Fig. 4) is intended to replace the rolling disk where that cannot be used of sufficient size.

A strong rectangular frame, e, carrying two strong uprights at its two extremities, is made so as to rotate with great facility around the vertical axis l. It supports the registering drum h with the clockwork arrangement f and a counterpoise, g. In practice it might be found advisable to attach these beneath the frame and so lower the centre of gravity of the whole apparatus. At a suitable distance above the drum a crossbar, p, is attached, which should be highly polished and square in section. The weight j should be made very heavy, and be allowed a very easy motion by means of four pairs of wheels, k, which are in contact with the crossbar p; these might be mounted on friction wheels (not shown in diagram). Attached on both sides of the weight are the silk threads $i\,i$, which traverse the upright, run over the pulley m, and are attached to the weights $o\,o$, which are only heavy enough to draw the weight j back to its place when it has been disturbed, that is to say, only just sufficient to overcome the friction of the wheels k. These weights, $o\,o$, are traversed by the guide wire n to prevent them dangling about during the swinging round of the frame.

The upper part of the frame carries two parallel bars, d, between which is a narrow groove to allow of the sliding of the plate c. They form the segment of a circle whose radius is equal to the length of the entire pendulum and its suspension. The pendulum a has fixed rigidly to its inferior extremity the steel axle b, which passes through the rectangular flat block c, which is prevented from slipping off by a bolt-head below, so that the flat block can rotate around the axle without falling off.

The action of the apparatus is as follows:—When an earth movement takes place the whole apparatus is brought into the azimuth of the wave-path by the oscillations of the pendulum a in that direction, which is affected by the block c sliding in the groove between the bars d. The pendulum should, in preference, have a short suspension, so that the period of its oscillations should be less than the wave intended to be registered by the apparatus, and should possess sufficient weight to have complete command over the frame, keeping it always in the wave-path azimuth. The weight will now appear to slide backwards and forwards on the bar p, registering its movements by the writing stylus, attached beneath it, on the drum h. The moment that j is moved from its central position one of the weights o is raised from its position of rest (these weights should preferably be hollow brass boxes into which only sufficient fine shot could be poured to overcome the friction of f), and rises as long as j continues to roll along the bar; if then the second half of the semiphase is not sufficient to bring it back to its normal position this will be done by o. When j has reached its central position, o will have come to rest at the base of the guide wire, and so no longer has any action, but is replaced in the second semiphase by its fellow of the opposite side. Of course the influence of the counterweights in retarding the rolling mass must be experimentally tried and taken into consideration in the calculations made from the tracings.

The principle of this instrument is the acceleration and retardation of a falling body during each semiphase of an earth-wave. Fig. 5 illustrates a means of registering such changes in the rate of a falling body so acted on, although some other person better acquainted with mechanical movements might possibly suggest some improvement.

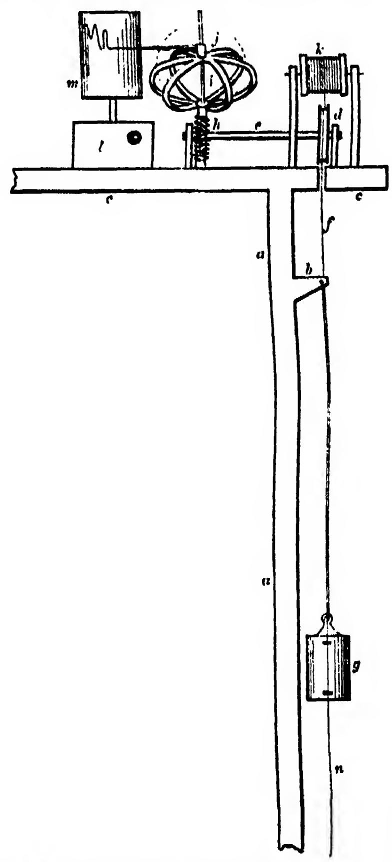

FIG. 5.—Apparatus for registering the vertical component of earth-waves during the whole of the disturbance.

A rigid vertical support of considerable length, a, is attached to the side of a well and is connected at its upper end to the table c; and by a small bracket b two vertical guide wires, n, pass through rings in the sides of the weight g, so far resembling Morin's apparatus illustrating the falling of bodies. Attached to the weight g is the silk thread f, which turns once or twice around the wheel d, and is supplied from the drum k. The wheel d is connected by the axle e and the continuous screw h to the apparatus i, which is a skeleton of flat steel springs, generally used to illustrate the distortion of a sphere by centrifugal motion. (I have proposed this in preference to the *ball governors* as retaining less impressed energy, which would unnecessarily complicate and even modify the results.) Sliding on the central axis of the spring sphere is a small cylinder, j, which is prevented from

rotating by means of a ridge on its inner surface and a corresponding groove on the upright bar. This cylinder carries the writing arm and stylus, which registers on the cylinder the rising and falling of the former; *l* is the motive power of the cylinder *m*. The apparatus for detaching the falling weight *g* is not shown in the diagram, but might be of the following arrangement:—A bob suspended by a spiral spring is made to make contact with a cup of mercury, as in the old form of vertical seismometers, besides a small lever of the first order attached at one end to the bob, the other extremity being above another cup of mercury. In this way, whether the movement of the bob be either up or down, in relation to the mercury cups, contact will be either made in the first case through the lever, or in the second directly by the bob. The current thus established could be used by an electromagnetic apparatus for removing a catch which holds the weight *g*. It could also start the cylinder *m* and stop a clock. The diagram will sufficiently explain the action of the apparatus.

If we review the advantages and disadvantages of the different instruments, I venture to say that, though far from perfection, they have much to be said in their favour. Their principal feature is the capability of registering continuously all the variations of the earth's movement during the complex disturbance known as an earthquake; that by employing large tracing drums with a spiral arrangement and time-ruled paper, accurate time-records can be obtained for a considerable period and without interruption, so that a single observer could have under his command a large number of instruments, even at stations some considerable distance apart, thus resulting in much economy of trained observers. Then again the records are all permanent, being graphically inscribed. The instruments for registering azimuth and amplitude, and capable of doing so with the greatest delicacy and friction, in all cases can be reduced to a minimum, or easily calculated. With regard to the registration of the vertical component of an earth-wave, the old form of spiral spring and bob principle may be excluded from consideration as perfectly unreliable; and even the improvements by Messrs. Milne and Ewing, and the ingenious idea of Mr. T. Gray, with its mercury trough compensator, cannot give accurate indication of the characters of a group of earth-waves. Another instrument worthy of trial is the hydrometer vertical-motion seismograph of Mr. T. Gray (*Phil. Mag.*, September 1881, p. 209). I think, however, that this instrument might be improved by using a long thin glass tube filled with air and floating in ether or some other fluid of very low viscosity. I would, however, venture to predict that a seismometer based on the principle of a falling weight, being accelerated or retarded according as the earth moves up or down, will supersede other methods, although no doubt such means of registering as described in this paper may be greatly improved upon.

The instruments described in this paper are all of considerable size, but it seems impossible to get good results unless heavy weights and their attendant mechanisms are used so as to reduce friction to a minimum in the consideration of results; for it is certainly a pity to have imperfect results in consequence of limiting the size of the apparatus. One great objection to the falling weight seismometer is the necessity for a deep well, to give sufficient time to register an earthquake of ten or twenty or even more seconds' duration; yet, by giving the weight more work to do by the introduction of multiplying wheels, this might be reduced as the circumstances might demand.

These instruments and the remarks on them are the outcome of long meditation while wandering over the ruins of two great earthquakes, and although expressed without a technical knowledge of mechanical construction, I hope I have made my ideas sufficiently clear.

H. J. JOHNSTON-LAVIS

INTERNATIONAL WEIGHTS AND MEASURES

In inviting attention to the work done at Sèvres during the past year by the Comité International des Poids et Mesures,[1] we are glad to have the opportunity of congratulating those interested in accurate measurement on the fact that this country is now to be represented on the Committee, and will thus have a voice in their discussions. This, as we have pointed out on previous occasions, appears to be required of a country so largely interested in scientific research as ours.

METRES

Description of Standard	Error in terms of the true standard metre (1μ = 10⁻⁶ m)	Mean coefficient of dilatation, 0° to t° C.
Standard I_2, which serves as the provisional standard of the Comité until the final prototype is verified ...	+ 6·00 μ	$10^{-9}(8594·6 + 1·26t)$
Standard I. for the use of the Bureau	+ 76·04	$10^{-9}(8602·9 + 2·09t)$
Standard II. for the use of the Bureau	+ 80·61	$10^{-9}(8569·1 + 2·79t)$
Standard III. for the use of the Bureau	+ 14·53	$10^{-9}(8560·0 + 1·63t)$
Standard XIII., belonging to French section of the Comité	+ 3·05	$10^{-9}(8540·6 + 2·62t)$
Bronze subdivided Standard N belonging to the Comité	48·58	$10^{-9}(17483 + 7·07t)$
Brass Barometer-Standard T_1 belonging to Comité, constructed by Société genevoise pour la Construction d'Instruments de Physique	− 7·2	$10^{-9}(18178 + 7·9t)$
Brass Barometer-Standard T_2	− 31·6	$10^{-9}(18213 + 7·2t)$
T_3	− 0·5	$10^{-9}(18037 + 4·7t)$
Brass Barometer-Standard constructed by Messrs. Hermann and Pfister, P...	− 149·3	$10^{-9}(18821 + 8·4t)$
Platinum Standard for Spain originally constructed by Froment with lines traced by J. Alfonso, Secretary to Standards Commission at Madrid, E	+ 4·95	$10^{-9}(8898)$
Iron Standard of the United States Government made by Repsold, US	+ 97·8	$10^{-9}(10563)$
Standard for Office of Weights and Measures at Vienna, II_A	+ 14·1	$10^{-9}(18708 + 3·00t)$
Standard for Office of Weights and Measures at Vienna, A_A	− 8·9	$10^{-9}(17971 + 3·15t)$
Iron Standard of Société genevoise, F	− 31·4	$10^{-9}(11063)$
Brass Standard of Société genevoise, L	− 62·6	$10^{-9}(19155)$
Bimetallic Standard for French War Department, constructed by Porro— Brass, C	− 111·8	$10^{-9}(18699)$
Steel, A	+ 31·1	$10^{-9}(10420)$
Copper Standard for M. Tresca, Cu	+ 10·7	$10^{-9}(16334 + 5·82t)$
Green Glass Standard made by M. Baudin for thermometric purposes, V	+ 128·2	$10^{-9}(8392 + 4·8t)$

KILOGRAMMES

	mgr.	mgr.
International kilogramme KI belonging to the Bureau ...	—	—
International kilogramme KIII belonging to the Bureau ...	KI—KIII = −0·1232	±0·0026
Kilogramme-type C belonging to the Bureau	C—KIII = +0·3217	±0·0034
Kilogramme-type S belonging to the Bureau	S—KIII = +0·4632	±0·0034
Standard kilogramme H for Spain	H—KIII = −1·8762	±0·0034
Standard kilogramme Z for Austria	Z—KIII = −1·3501	±0·0034

The present volume, like its two predecessors, is published by the Director of the Bureau under the authority of the Comité, and contains some account of the modes of comparison of the standards, with descriptions of the apparatus used, and a complete statement of the observations and of the methods of their reduction. The work of the Bureau has mainly included determinations of the lengths of certain standard metres and of the weights of certain standard kilogrammes for different Governments and authorities, as shown in the above tables.

These tables do not include the important comparisons of the British Standards with those of the Bureau, an account of which is given in a Report presented to Parliament by the Board of Trade last year, and in the Report of the Proceedings of the Committee for 1883.

The comparisons of the metres by Dr. René-Benoit, and those of the kilogrammes by M. Marek, were made in the same manner and after the same methods as those described in vols. i. and ii., to which we have previously referred.

M. Marek gives a thoughtful description of the excellent normal barometer and cathetometer in use at the Bureau, as well as of the methods of calibrating the thermometers used during the weighings. There are also illustrations of the apparatus used in ascertaining specific gravities, and of M. Stas's method for clearing the surfaces of metals by a jet of alcohol vapour, of which we regret that the demands on our space do not allow an account.

The many pages of observations and calculations which are given in this volume are clearly arranged and carefully printed. We doubt, however, whether it may be desirable to publish so much detail, particularly all the observations of the balances. Each Report of verification should evidently include all the observations, &c., from which the results have been obtained, but it would appear to be necessary only that the Government or authority directly interested should be furnished with a full detailed Report. Economy of time and money might be effected to readers and purchasers, and perhaps the objects of the Comité further advanced, by the omission in such publications of any unnecessary detail.

NOTES

THE Washington Prime Meridian Conference has adopted a solution declaring the universal day to be the mean solar day, beginning, for all the world, at the moment of mean midnight of the initial meridian, coinciding with the beginning of the civil day, and that meridian to be counted from zero up to twenty-four hours. The resolution further declares that the Conference expresses the hope that, as soon as practicable, astronomical and nautical days may be arranged everywhere to begin at mean midnight. Prof. Janssen, of France, moved that the Conference should express the hope that technical investigations to regulate and extend the application of the decimal system to the divisions of the circle and of time would be resumed, in order to permit of the extending of that application to all cases where it might present real advantages. The motion was adopted, and the Conference adjourned until Wednesday.

M. BERTRAND, the Perpetual Secretary of the Paris Academy of Sciences in the Mathematical Section has been proposed as a candidate to fill the place vacated by the death of M. Dumas in the Académie Française. His nomination is certain, and will take place without opposition. It is almost customary for the Académie Française to offer a seat to one of the secretaries of the Academy of Sciences; Delambre, Fourier, Flourens, Cuvier, and Dumas enjoyed this honour in succession. Arago was offered it several times, but obstinately refused it. He strictly adhered to the old constitution of the Institut National as created by the Directory of the First Republic, which states that the five sections constitute the several parts of a living encyclopædia established to deliberate *in common* on many different questions, and that consequently no member of one section should be eligible to another. When the Restoration took place, the Institut was divided into independent academies, and the old practice of electing a person to several of them was revived. It has not been altered since 1848, although several attempts have been made in order to recall into existence the former republican organisation.

ON the night of Saturday, October 4, some interesting observations of lunar coronas and fog-bows were made at Ben Nevis Observatory. The mountain-top had been enveloped in mist for several days previously, but about 9 p.m. it began to clear, and by 11 o'clock the moon, partially eclipsed, was visible, surrounded by a strong double corona; all the colours from red to blue being seen in both rings. Measurements of these were taken by Mr. Dickson, Interim-Superintendent, with an instrument designed for the purpose by Prof. Tait. These gave:—Outer diameter of red—outer ring, 7° 46′; inner ring, 4° 52′. After midnight the sky became quite clear and the moon shone brightly, no corona being visible. At times, however, detached portions of very thin mist came up the north-west side of the mountain and brushed over the top. Whenever this occurred a strong corona again surrounded the moon, with a *third* set of rings, outside the other two, and much fainter, but sufficiently bright to allow of all the colours being distinguished. At 1.30 a.m. on October 5 the outer set of rings was more distinctly marked than before, and measurements were again taken. These gave:—Outer diameter of red—inner ring, 4° 6′; middle ring, 6° 2′; outer ring, 8° 10′. All these measurements are subject to an error of not more than ± 6′. At 1.15 a.m. a lunar fog-bow was visible on a fog bank to the northwards. From the edge of the precipice to north-north-east of the Observatory this appeared to consist of an outer ring, having a diameter of 75°, and an inner and fainter ring, diameter 65°, the space between the rings appearing almost quite dark, as if caused by a sharply-defined break in the fog. No colours could be distinguished.

FROM the *Alta California* we learn that the Lick Trustees have just received, through the kindness of Capt. Goodall, of the firm of Goodall, Perkins, and Co., important advices from Paris in regard to the glass disk which is needed to complete the 36-inch equatorial for the Lick Observatory. It will be remembered that the contract for two disks—one of flint and the other of crown glass—which are needed for the construction of an achromatic objective, was let to the celebrated firm of Alvan Clark and Sons in 1861. There were only two firms in the world who were capable of making glass disks of such size, nearly 40 inches in diameter. The Clarks employed one of these, Messrs. E. Feil and Co. of Paris, to cast the rough disks for them. The flint disk was cast in an unexpectedly short time, but the making of the crown glass disk has proved to be a matter of great difficulty, and this alone will have delayed the making of the large objective, and thus the completion of the Lick Obser-

vatory, by several years. The Lick Trustees will have all the Observatory, excepting the large telescope and the dome to contain it, finished and ready for work during 1885. As soon as two perfect disks of crown and flint glass are on hand, the focal length of the telescope can be calculated, and the size of the great dome determined upon; and nothing can be done until this focal length is known. Nineteen trials have been made by the Messrs. Feil to cast a perfect crown disk, and a delay of more than two years has been incurred through the difficulties and risks of the operation. It appears from the letter of Capt. Goodall to Capt. Floyd, which has been referred to, that Messrs. Feil have cast two disks, which they expect to be suitable for the purpose. The Captain visited their works early in September, and they were expected to ship one of the disks to Clark and Sons early in October. There is then reason to believe that the rough disks for the large telescope will soon be in the hands of the optician. The successful working of these disks into the proper curve for a perfect object-glass is a matter of the greatest difficulty, but the extraordinary skill which the Clarks have acquired leave no doubt that within two or three years after the receipt of a perfect disk the whole 36-inch objective (the largest possible) will be finished. While the objective is making, the dome and the mounting can be constructed, so that the whole delay is and has been due to the difficulties incident to the opticians' work. The work on Mount Hamilton has progressed as far as possible under the present conditions, and it will not be long before California possesses the most perfect observatory in the world, placed in the most favourable situation which can be found.

THE recent works of the United States Geological Survey, and especially the remarkable report of Capt. Dutton, have given an opportunity to Prof. Trautschold of Moscow, to draw a parallel between the geological structure of Colorado and that of European Russia, which appears in the *Bulletin* of the Moscow Society of Naturalists. In Russia, the Silurian, Devonian, Carboniferous Limestone, and Lower Permian series are marine deposits, while the Upper Permian is of fresh-water or terrestrial origin. The Trias and Lower Jurassic rocks are also continental deposits,—or seem to be so to a great extent,—while the Upper Jurassic groups are again of marine origin, as is also the Chalk, which contains only islands with land-vegetation. Three parts of the Tertiary series consist of terrestrial and fresh-water deposits, marine deposits appearing only in the south; and the Quaternary is also a continental formation. Such being, according to Prof. Trautschold, the structure of Russia, he had already concluded that in the Northern Hemisphere there was a general retreat of the sea during Palæozoic times, and a growth of continents, upon which the Carboniferous and then the Permian floras largely increased, European Russia being, during the Triassic and the first half of the Jurassic periods, a continent with nearly the same outlines as now. During the second half of the Jurassic period, another subsidence of the continent, and an advance by it into the Northern Hemisphere, again took place, without reaching, however, the same level that it had had during the Palæozoic period; the sea remaining shallow. A second retreat of the water took place during the Tertiary and Quaternary periods. Similar oscillations might well explain, in Prof. Trautschold's opinion, the structure of the Grand Cañon district, where the connection between the Jurassic and Triassic is as close as in Russia.

THE next ordinary general meeting of the Institution of Mechanical Engineers will be held in the large Lecture Theatre, University College, Shakespere Street, Nottingham, on November 5. The chair will be taken at 4 p.m., by the President, I. Lowthian Bell, F.R.S. The following papers will be read and discussed, as far as time will admit:—On the Mineral Wagons of South Wales, by Mr. Alfred Slater, of Gloucester; on the Application of Electro-Magnets to the working of Railway Signals and Points, by Mr. Illius A. Timmis, of London; Second Report on Friction Experiments, by Mr. Beauchamp Tower, of London.

THE International Congress convened to deliberate upon the best means of preventing the spread of *Phylloxera vastatrix* was opened on Monday at Turin. Among the personages present were the Duke d'Aosta, Signor Grimaldi, Minister of Commerce, the Syndic of Turin, and the French, Greek, Spanish, Portuguese, Servian, and Roumanian Delegates to the Congress. After a short address of welcome from the Syndic of Turin, Signor Grimaldi explained the object of the Congress, and dwelt particularly upon the necessity of common legislative measures being adopted in all infected countries in such a form as not to interfere with the liberty of trade. It was, however, most requisite to raise barriers to the spread of the Phylloxera.

THE last issue of the *Transactions* of the Seismological Society of Japan (vol. vii. part 1) contains a paper by Prof. Milne on Earth Tremors, dealing successively with artificially produced tremors, natural tremors, and at some length with various instruments constructed to record these minute movements. Microseismology, by the way, appears to be the name of this new branch of science. The results which have been obtained so far do not appear to be of great importance. The motions are more law-abiding than earthquakes; but it is impossible to say yet whether their systematic study will enable us to foretell an earthquake, although from examples quoted it appears that earthquakes are frequently preceded by great microseismic activity. Nor is the cause of these constant movements understood. Among the theories on this subject mentioned by Prof. Milne is one that they may be due to slight vibratory motions produced in the soil by the bending and crackling of rocks caused by their rise upon the relief of atmospheric pressure. Rossi thinks they may be the result of an increased escape of vapour from the molten material beneath the crust of the earth consequent upon a relief of external pressure. In the same number Dr. Du Bois writes on the great earthquake of Ischia; and a catalogue of earthquakes in Tokio between July 1883 and May 1884, as observed by a Palmieri's seismograph, is also given. From the annual report of the Society we observe that the committee appointed to report on a system of earthquake observations give as their conclusion that the most important observation is that of time, and experiments are now being carried out to obtain a suitable clock for this purpose. The next number is to contain an important paper by Prof. Milne giving a detailed account, with a series of maps, of 387 earthquakes recently felt in Northern Japan.

MR. SPENCE PATERSON, H.B.M. Consul at Reykjavik, writes to the *Standard* that on September 9 he visited Cape Reykjanes, the south-west point of Iceland, in order to observe the volcanic island which recently appeared off that Cape. It was first seen by the light-keeper at Reykjanes on July 29, and had then the shape of an irregular truncated cone, with a slight hollow on the top and a projecting shoulder on the north side. No earthquakes or other volcanic manifestations accompanied its appearance, but on August 5 a series of severe shocks occurred, which split the walls of the lighthouse and damaged the lamps. For several days rain and fog obscured the island; when next seen, its shape had altered; part of the south side had fallen down into the sea, forming two little mounds, and leaving a steep, almost perpendicular face on the south. The height of the island is about two-thirds of its length. It lies about west-south-west of Reykjanes. Two officers of a French war-vessel, who recently visited Reykjanes, estimate its distance from the coast at nine or

en miles, but Mr. Paterson believes it to be considerably greater. When first seen, the upper part of the island was perfectly black, but it has now begun to whiten, owing to the droppings of the myriads of sea-fowl which frequent the adjacent coast and neighbouring islands, and seem already to have taken possession of the new land. The neighbourhood of Reykjanes is noted for volcanic manifestations—islands have from time to time risen and sunk there, and only a couple of years ago a violent eruption occurred near the spot where the new island lies; columns of smoke and steam rose out of the sea, and large quantities of pumice were thrown up and floated ashore on the neighbouring coast.

It is stated that in consequence of the immense success obtained by the opening of the Arlberg Tunnel, France has confidentially sounded the Swiss Federal Council as to piercing the Alps at the Simplon.

A FATAL gas explosion took place in Paris four months ago near the Porte St. Denis, under circumstances quite similar to the accident which took place in Bermondsey last week. Since that time the Prefet de la Seine has appointed a Commission to determine the best manner of searching for gas escapes. An electric lamp fed with a portable accumulator has been selected and rendered obligatory for such operations. This apparatus has been described at length in the French illustrated papers. It might perhaps be improved, but the principle is quite sound, and it is to be regretted that the results of the French experiments have not become known in England.

We have received a communication from Prof. M. Nyrén, Director of the Imperial Observatory at Pulkowa, near St. Petersburg, informing us that the weather there was so cloudy that not a vestige of the moon could be seen on the occasion of the recent total eclipse. In Helsingfors, where Prof. Nyrén happened to be that night on his return journey from abroad, he could distinguish the darkening of the moon's disk through the clouds, but it was too thick to observe the eclipse of the stars. At Dorpat, the second great Russian Observatory, the weather was also entirely unfavourable for observations. This is greatly to be regretted, in view of the elaborate preparations made by the Russian astronomers, to which we referred last week.

The Royal Bohemian Society of Sciences will celebrate its hundredth anniversary at Prague on December 6 next.

The new University building at Vienna was completed on the 11th inst. The new building at Strasburg will be inaugurated on the 26th inst.

The death is announced of Dr. Robert Ave-Lallemant, well known as a traveller in Brazil, who was born at Lübeck in 1812. He died there on October 10. Also of Dr. Wilhelm Gonnermann, a naturalist who, together with Dr. Rabenhorst edited the celebrated "Mycologia Europæa." He died at Coburg, aged seventy-eight years.

The French Minister of Public Instruction has commissioned M. Brau de St. Paul Lias to proceed to Malacca and Sumatra for the purpose of making natural history collections. M. Étienne Gautier is to do the same in Persia and Asiatic Turkey; and Dr. Guardia goes to the Balearic Isles to study the dialect there.

The life of a Ceylon planter appears to be a constant contest with insect pests of one kind and another. A short time since we noticed a correspondence on a "blight" which attacked the tea-plant, and now the Ceylon papers which arrived by the last mail contain a report, by Dr. Trimen, the head of the Botanic Gardens in the colony, on an insect which has caused much alarm by its depredations on cacao and cinchona plantations. He thinks the only serious damage to cacao comes from the *Helopeltis antonii*, which appears to be a recent importation to Ceylon, although well known in Java. It is believed to be still in small numbers, and to be confined to certain localities, and the only remedy suggested by Dr. Trimen is that the planters should have it carefully sought for and destroyed.

We are requested to announce that in future the ordinary meetings of the Essex Field Club will be held in the large hall of the Public Hall, Loughton, Essex. The first meeting of the winter session will be on Saturday next, the 25th inst., at seven o'clock.

A Society has been established at Vladivostok in Eastern Siberia for the purpose of exploring the Amour district, with a view of founding in Vladivostok a museum illustrative of the natural history of the region.

The additions to the Zoological Society's Gardens during the past week include a Meadow Pipit (*Anthus pratensis*), six Twites (*Linota flavirostris*), a Linnet (*Linota cannabina*), eight Lesser Redpolles (*Linota rufescens*), British, presented by Mr. T. E. Gunn; two Robben Island Snakes (*Coronella phocarum*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Hardwick's Mastigure (*Uromastix hardwickii*) from India, presented by Mr. Cuthbert Johnson; a Moustache Monkey (*Cercopithecus cephus*) from West Africa, a Greater Sulphur-crested Cockatoo (*Cacatua sulphurea*) from Australia, a Blue and Yellow Macaw (*Ara ararauna*) from South America, deposited; six Coypus (*Myopotamus coypus*), three Cockateels (*Calopsitta novæ-hollandiæ*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

Wolf's Comet.—The observations of this comet to the end of September having been found irreconcilable with parabolic motion, Prof. Krueger, the editor of the *Astronomische Nachrichten*, and Mr. S. C. Chandler, jun., of Harvard College, have investigated the elements by a general method, and find an elliptic orbit of very limited dimensions, the period of revolution being 6·55 years by Prof. Krueger's calculation, and 6·65 years by Mr. S. C. Chandler's. Other elements by the former calculation are as follows:—

Perihelion passage 1884 November 17·8999 G.M.T.

	°	′	″	
Longitude of perihelion	19	20	56	M.Eq. 1884·0
,, ascending node	206	35	35	
Inclination	25	3	54	
Angle of eccentricity	33	32	29·7	
Log. semi-axis major	0·544040			
Log. perihelion distance ...	0·194792			

In such an orbit there would be a very close approach to the orbit of Jupiter in about 209° heliocentric longitude, where the distance between the two would be less than 0·12, and with Prof. Krueger's period of revolution there would be great perturbation early in the year 1875, so that it is possible the comet may not have been moving long in its present track. It will be interesting to examine this point further, when the major axis of the comet's orbit has been more accurately determined by a wider extent of observation.

We have thus two comets of short period brought to light in the same year. As regards Barnard's comet the length of revolution appears to be yet somewhat doubtful, Prof. Morrison of Washington assigning 6·43 years, and Dr. Berberich of Strasburg 5·50 years only.

The November Meteors.—Assuming that these bodies are moving strictly in the orbit of the first comet of 1866, we find by Prof. Oppolzer's definitive elements that the nearest approach to the orbit of Mars is in about heliocentric longitude 0°·5, distance 0·30; the nearest approach to the orbit of Jupiter is in 198°·7, distance 0·79; in the case of Saturn the least distance of orbits is 0·46 at 214°·9; and in that of Uranus 0·37 at 234°·2. In 1866 the comet traversed the plane of the earth's orbit in 51°·4, distant therefrom only 0·0066.

NEW SOUTHERN DOUBLE-STARS.—Mr. H. C. Russell, Government Astronomer at Sydney, has circulated a list of newly-detected double-stars, some found by himself with the large instrument, and others by Mr. Hargrave with the 7½-inch equatorial. In most cases the components belong to the tenth and eleventh magnitudes.

THE TOTAL SOLAR ECLIPSE OF 1816, NOVEMBER 19.—The first total eclipse of the sun in the present century in which the central line passed over Europe took place on the morning of November 19, 1816. Maps of its track appeared in the *Berliner Jahrbuch* for 1816, and in the first part of Hallaschka's *Elementa Eclipsium*, where the full computation of this eclipse is given as an example. In Lindenau and Bohnenberger's *Zeitschrift für Astronomie*, vol. v., Hagen gives the moon's place deduced from Burckhardt's Tables, with the horizontal parallax and semi-diameter: if we combine these with similar quantities for the sun, taken from Carlini's Tables of 1833, we find the following elements of the eclipse:—

G.M.T. of Conjunction in R.A. 1816 Nov. 18 at 21h. 46m. 57s.

	°	′	″	
R.A.	234	42	20	
Moon's declination	18	37	9	S
Sun's ,, ...	19	30	29	S
Moon's hourly motion in R.A.... ...		36	58	
Sun's ,, ,, ..		2	37	
Moon's ,, ,, Decl.... ...		11	37	S
Sun's ,, ,, ,, ...		0	38	S
Moon's parallax		60	15	
Sun's ,, ...		0	9	
Moon's semi-diameter		16	25	
Sun's ,, ,, ...		16	12	

In the *Berliner Jahrbuch* Bode makes the eclipse total at both Dantzic and Warsaw; the above elements do not show totality at either place, but give the magnitudes 0·990 and 0·992 respectively. They indicate, however, a total eclipse at Bromberg, duration 1m. 22s. Possibly there may be other observations of the totality on record, but the only one we have found was made by Hagen at Culm in Bohemia, where he observed its commencement but not the ending. It would appear that the weather at this season was an impediment to observation, or more details of the total phase in its passage over Germany might have been expected. Before the eclipse of July 1842 there was only one in which the line of totality approached near the European continent, viz. that of July 17, 1833, which was total in Iceland; on Mount Hecla the total eclipse commenced at 4h. 56m. 37s. a.m., and continued two minutes, the sun at an altitude of 13°; but the days of physical observations had not then arrived, and we do not find it recorded that a midsummer expedition to Iceland was organised.

CHEMICAL NOTES

THERE has of late been a considerable amount of work done on the relations between the composition and structure of chemical compounds and various physical constants of these compounds; and also on the relations between the conditions of chemical change and some of the physical properties of the constituents of the changing systems. Among the more important work on the former class of relations are to be mentioned Perkin's researches on the *magnetic rotatory polarisation* of compounds (*C. S. Journal, Trans.* for 1884, p. 421 *et seq.*); and Schiff's researches on the *coefficients of capillarity* of liquid carbon compounds (*Annalen*, ccxxiii. 47). The investigations of Raoult on the connections between the freezing-points of solutions and the distribution of the salts therein form an important contribution to the study of the second group of relations (see especially *Ann. Chim. Phys.* (6), ii. p. 66, *et seq.*). Perkin has measured the rotations of the plane of polarisation of a ray of monochromatic (sodium) light, produced by passing the ray through columns of various liquid carbon compounds placed between the poles of a large electro-magnet. Then, by the use of the formula $\frac{r \times M}{d}$, where r = observed rotation, d = density, and M = molecular weight (as gas), of the given compound, he has calculated the magnetic rotatory effect of unit-length of the liquid obtained by condensing unit-length of the vapour of the same liquid. The observed results are thus referred to lengths of liquid related to each other in the ratio of the molecular weights of the various compounds examined. Each result is divided by the number obtained, by the same method, for water, and the quotient represents the *molecular rotatory power* of the given compound. The molecular rotatory powers of a great many compounds belonging to twenty-six series have been determined, and the results show that the constant in question is closely connected with the valencies of the atoms, and with the distribution of the interatomic actions, in the molecules of the compounds examined. Schiff has made an extended series of determinations of the *coefficients of capillarity*, that is the capillary elevations in tubes 1 mm. radius, of many liquid carbon compounds. By multiplying this constant by the density of the compound, and dividing by 2, another constant is obtained which represents the weight of liquid raised by capillary action through unit-length of the line of contact between the liquid and the containing vessel. Lastly, by dividing the coefficient of capillarity by twice the "molecular volume" $\left(i.e. \ \frac{\text{molecular weight of gas}}{\text{density of liquid}}\right)$, a quotient is obtained which represents the relative number of molecules raised along the line of contact between the liquid and solid surfaces. Schiff's results, although very numerous, do not yet allow very definite conclusions to be drawn regarding the connection between the three constants and the molecular structure of the compounds examined; but that a definite connection exists is rendered very probable by these investigations. Raoult has made many determinations of the *molecular lowering of the freezing-point*—that is, the lowering of the freezing-point produced by the solution of 1 gramme-molecule of substance dissolved—of various solvents by acids, bases, and salts. The solvents employed were water, benzene, nitro-benzene, ethylene dibromide, acetic and formic acids. In each case the molecular lowering of the freezing-point is approximately equal to one of two values, of which one is double the other. The acids examined may be divided into two groups as regards their effect on lowering the freezing-point of water. The value of the constant measured by Raoult is approximately 40 for one of the groups, and 20 for the other group. The bases examined likewise fall into two groups; the mean values of the constants being 39 and 19 respectively. Raoult states that the acids with the higher value (40) almost completely displace the acids with the lower value (20) from their combinations with bases, when the acids and salts react in equivalent quantities. The bases of the first group almost completely displace those of the second from their combinations with acids. Measurements of the molecular lowering of the freezing-point of water by the action of acids, bases, and salts, present us with data from which, according to Raoult, the distribution of the various acids, &c., in a changing chemical system may be deduced.

AMERICAN ORNITHOLOGISTS' UNION

THE second annual meeting of the American Ornithologists' Union was held in the American Museum of Natural History, New York City, September 30 to October 2, 1884, the President, Mr. J. A. Allen, in the chair.

The Active Members present were: J. A. Allen, H. B. Bailey, Chas. F. Batchelder, Eugene P. Bicknell, William Brewster, Montague Chamberlain, Dr. Elliott Coues, D. G. Elliot, Dr. A. K. Fisher, Col. N. S. Goss, Dr. J. B. Holder, Dr. C. Hart Merriam, Robert Ridgway, Thomas S. Roberts, John H. Sage, George B. Sennett, Dr. Leonhard Stejneger.

Dr. Philip Lutley Sclater, Mr. Howard Saunders, and the Rev. E. P. Knubley, of the British Ornithologists' Union, were also present, and were cordially invited to take part in the proceedings of the Union.

The Associate Members in attendance were William Dutcher, Fred T. Jencks, and Dr. Howard Jones.

On the recommendation of the Council the following persons were elected to Foreign Membership:—Heinrich Gätke, Heligoland; Dr. W. Taczanowski, Russia; Henry Seebohm, England; Howard Saunders, England; Dr. H. Burmeister, Brazil.

The following among others were elected Corresponding Members:—Dr. John Anderson, F.R.S., India; W. T. Blanford, F.R.S., London; Major H. W. Feilden, London; Dr. Hans Gadow, England; Col. H. H. Godwin-Austen, London; Dr. Julius von Haast, New Zealand; Dr. E. Holub, Austria; Dr. C. F. Homeyer, Germany; E. L. Layard, New Caledonia; Dr. A. B. Meyer, Germany; Dr. A. von Mojsisovics, Gratz; Dr. A. J. Malmgren, Finland, Dr. A. von Middendorff,

Russia; Col. N. Przevalsky, Russia; Dr. Gustav Radde, Russia; Dr. Leopold von Schrenck, Russia; Dr. W. Severtzow, Russia; Rev. Canon H. B. Tristram, England; Dr. Hjalmar Theel, Sweden.

The report of the Committee on Revision of Nomenclature and Classification of North American Birds was presented by the Chairman, Dr. Elliott Coues, who said that the work of the Committee had been divided by the creation of two Sub-Committees: one (consisting of Messrs. Ridgway, Brewster, and Henshaw) to determine the status of species and sub-species; the other (consisting of Mr. Allen and Dr. Coues) to formulate the canons of nomenclature and classification adopted by the Committee. He also expressed the indebtedness of the Committee to Dr. Leonhard Stejneger for determining many points in synonymy, and for other aid. Dr. Coues then read at length the report of the Sub-Committee on Codification of Canons of Nomenclature and Classification, as adopted by the full Committee. The reading occupied about an hour and a half. Mr. Ridgway continued the report by reading the list of species prepared by the Sub-Committee on the Status of Species and Sub-Species as adopted by the full Committee. The Committee unanimously adopted the tenth edition of Linnæus's "Systema Naturæ" as the starting-point in zoological nomenclature; it unflinchingly avowed its adherence to the rule of priority; and emphatically and unequivocally indorsed the employment of trinomials in the designation of sub-species.

The report of the Committee on Bird Migration was presented by the Chairman, Dr. C. Hart Merriam. Dr. Merriam stated that a circular had been issued setting forth the objects and methods of the Committee, specifying the division of the territory of the United States and British North America into thirteen districts (each of which had been placed in charge of a competent superintendent), and supplying instructions to observers concerning the data desired—which were classed under the heads of Ornithological, Meteorological, and Contemporary and Correlative Phenomena.

In order to secure a large number of observers, the Chairman had written to the editors of eight hundred newspapers, asking them to call attention to the work of the Committee and to state that more observers were desired. The several superintendents had also written to a large number of papers—just how many the Chairman was not aware. The Press very kindly gave the matter the prominence its importance deserved, and abstracts of the circulars, amounting in some cases to an actual reprint, and usually coupled with editorial comment, were published in several hundred newspapers. This resulted in the receipt by the Chairman of upwards of three thousand applications for circulars of information and instruction. In all, nearly six thousand circulars were distributed. By this means the Committee finally secured nearly seven hundred observers, in addition to the keepers of lights. The observers are distributed as follows:—Mississippi Valley district, Prof. W. W. Cooke, Superintendent, 170; New England district, John H. Sage, Superintendent, 142; Atlantic district, Dr. A. K. Fisher, Superintendent, 121; Middle-Eastern district, Dr. J. M. Wheaton, Superintendent, 90; Quebec and the Maritime Provinces, Montague Chamberlain, Superintendent, 56; district of Ontario, Thomas McIlwraith, Superintendent, 38; Pacific district, L. Belding, Superintendent, 30; Rocky Mountain district, Dr. Edgar A. Mearns, Superintendent, 14; Manitoba, Prof. W. W. Cooke, Superintendent, 10; British Columbia, John Fannin, Superintendent, 5; North-West Territories, Ernest E. T. Seton, Superintendent, 5; Newfoundland, James P. Howley, Superintendent (returns not yet received). Migration stations now exist in every State and Territory in the Union excepting Delaware and Nevada.

The Committee was fortunate in obtaining the co-operation of the Department of Marine and Fisheries of Canada, and of the Lighthouse Board of the United States. By this means it secured the free distribution of upwards of twelve hundred sets of schedules and circulars to the keepers of lighthouses, lightships, and beacons in the United States and British North America.

The returns thus far received from observation were exceedingly voluminous and of great value. They were so extensive, indeed, that it was utterly impossible for the Committee to elaborate them without considerable pecuniary aid.

In order to show the Union the character and extent of the labours of the Committee, the Chairman had requested the superintendents of all districts east of the Rocky Mountains to prepare reports upon five common, well-known, and widely-distributed birds, to wit: the robin (*Merula migratoria*), catbird (*Mimus carolinensis*), Baltimore oriole (*Icterus galbula*), purple martin (*Progne subis*), and nighthawk (*Chordeiles popetue*). This had been done, and the reports received were presented for examination. The Chairman directed special attention to those prepared by Dr. J. M. Wheaton and Dr. A. K. Fisher as examples of tabulated returns, and to that received from Prof. W. W. Cooke as an example of the generalisation of results.

The Chairman called attention to the action of the International Ornithologists' Congress held in Vienna last April, stating that he had been instructed (in common with the delegates from other countries) to represent the cause of the Committee in the National Government, begging it "to further to the utmost the organising of migration stations," and "to appropriate a sufficient sum for the support of these stations, and for the publication of annual reports of the observations made."

The Council was instructed to memorialise the Congress of the United States, and the Parliament of Canada, in behalf of the work of the Committee on Bird Migration.

On the motion of Mr. Brewster, the Committee on Geographical Distribution was merged into the Committee on Migration as a Sub-Committee, the whole Committee to be entitled a "Committee on the Migration and Geographical Distribution of North American Birds."

The Report of the Committee on the Eligibility or Ineligibility of the European House-Sparrow in America was presented by Dr. J. B. Holder, Chairman of the Committee. Dr. Holder said that a circular of inquiry had been printed, and about one thousand copies circulated in Canada and the United States. Particular pains had been taken to secure evidence from those who advocated the cause of the sparrow. A large number of returns had been received, and the evidence for and against the naturalised exotic had been carefully sifted and summarised. The result overwhelmingly demonstrated that the sum of its injurious qualities far exceeds and cancels the sum of its beneficial qualities. In other words, it was the verdict of the Committee that the European house-sparrow is not an eligible bird in North America. The Union sustained the decision of the Committee.

The Report of the Committee on Faunal Areas was presented by the Chairman, Mr. J. A. Allen. Mr. Allen said that, for the purposes of the Committee, North America had been divided into several districts, each of which had been placed in charge of a member of the Committee as follows:—Arctic and British America and the northern tier of States bordering the Great Lakes, from New York to Minnesota inclusive, were being worked by Dr. C. Hart Merriam; Canada, south of the St. Lawrence, and New England, by Arthur P. Chadbourne; the Eastern and Middle States, from New Jersey to Florida, and west to the Mississippi River, by Dr. A. K. Fisher; the Rocky Mountain region by Dr. Edgar A. Mearns; and the Pacific region by L. Belding. It was the plan of the Committee to collate and tabulate the required data from all published sources; to avail itself in like manner of the material contained in the returns of the observers of bird migration (this privilege having been granted by the Committee on Bird Migration); to illustrate the facts thus obtained by coloured maps showing the summer and winter range of each species; and to generalise the final results and place the same before the Union, accompanied by coloured charts showing, with as much precision as possible, the exact limits of the several *faunal areas* in North America.

Dr. P. L. Sclater said he was glad to know that North America, which he knew as a *Nearctic* region, was being worked in so thorough a manner by so competent a Committee, and that the results obtained could not fail to be of great interest and value.

The matter of the wholesale slaughter of our native birds for millinery and other purposes was brought forcibly before the Union by Mr. Wm. Brewster, and a Committee was appointed for the protection of North American birds and their eggs against wanton and indiscriminate destruction.

Dr. Merriam spoke of the capture, just two weeks previously (September 19), of a second specimen of the wheatear (*Saxicola œnanthe*) at Godbout, on the north shore of the St. Lawrence, by Mr. Napoleon A. Comeau. Mr. Comeau exhibited the bird, a handsome male, and said that he shot the first specimen at the same place on May 18 last. He also spoke of the capture at Godbout of the European house-sparrow (*Passer domesticus*), thus extending the known range of the species, on the north shore, by at least 250 miles.

Dr. Leonhard Stejneger exhibited a stuffed specimen of a willow grouse from Newfoundland, which he regarded as a new geographical race, differing from the continental form chiefly in the possession of more or less black upon its primaries. Mr. Brewster said that he had recently examined 150 specimens of ptarmigan from Newfoundland, and had observed the peculiarities pointed out, but did not consider them constant. He was inclined to regard the characters mentioned as seasonal, and possibly to some extent individual. Dr. Stejneger replied that this coloration of the wing feathers could not possibly be seasonal as they (the primaries) were moulted but once a year. Dr. Merriam stated that during a recent visit to Newfoundland he had examined a very large number of willow grouse in the flesh, and was still engaged in investigating the change of colour in this species. His studies led him to disagree with Dr. Stejneger's last statement. He (Dr. Merriam) was convinced that change in colour in individual feathers did take place, both independent of and coincident with the moult. Mr. D. G. Elliot agreed with Mr. Merriam in considering the change of colour of individual feathers an established fact. An animated discussion followed, and was participated in by Messrs. Brewster, Comeau, Coues, Elliot, Merriam, Ridgway, and Stejneger.

In response to a call from the President, Dr. P. L. Sclater said:—

"I hope the members of the American Ornithologists' Union will excuse me if I offend the feelings of any one by the remarks I am about to make. It has aggrieved me much to find in this country three large and valuable collections of birds which are not under the care of paid working ornithologists. One of these is in Boston, one in New York, and the other in Philadelphia. Each contains what all ornithologists admit to be most valuable typical specimens. A grave responsibility rests upon the possessors of types of species, and the loss or injury of such specimens is a great and irreparable loss to science. The collection of the Boston Society of Natural History (known as the La Frenayé Collection) has been much damaged by neglect, and the entire collection ought to be catalogued and so arranged as to render any particular specimen readily accessible. In this building (the American Museum of Natural History in New York) are the types of the celebrated Maximilian Collection, and many other specimens of exceeding great value. A large number of these have never been properly identified, and some of them are missing and have doubtless been destroyed by insect pests. The value of others has been lost through neglect, by the displacement of labels, and by the omission of proper measures for their preservation. The same remarks would, in a general way, apply to the collections of the Philadelphia Academy of Natural Sciences. It is sad to find no paid ornithologists in charge of these exceedingly valuable collections, and I beg to suggest that the American Ornithologists' Union can undertake no worthier task than to impress upon the proper authorities the urgent necessity of immediate action in this matter."

The officers of the Union were re-elected as follows:—President, J. A. Allen, Cambridge; Vice-Presidents, Dr. Elliott Coues and Robert Ridgway, Washington; Secretary and Treasurer, Dr. C. Hart Merriam, Locust Grove, New York.

The place of meeting for next year was referred to the Council for decision.

THE CAPILLARY CONSTANTS OF LIQUIDS AT THEIR BOILING-POINTS

The paper of Prof. Robert Schiff, published in *Liebig's Annalen*, March 1884, on this subject, marks the first successful attempt out of many that have been made to connect the surface-tension of a liquid with its molecular constitution.

It has long been known that the tension diminishes rapidly with a rise of temperature, but the importance of this fact when it is desired to make a comparative examination of different liquids has not been fully appreciated or sufficiently insisted on till now by Prof. Schiff, who has to lament that, out of the considerable array of experimental investigations on the subject which he has examined, very few results could be extracted which could be usefully employed in such a comparative study, a failure which he attributes to the completely arbitrary and dissimilar physical conditions under which the different substances in question have been examined.

Since it is impossible to compare surface-tensions at the critical point, because that is the point at which the surface-tension vanishes, it is necessary to seek some other condition in which different liquids may be physically comparable, and that which naturally suggested itself for trial to Prof. Schiff, was the boiling-point of the liquid itself, whose significance in this respect he has himself established.

The principle of his method was to select with great care two capillary glass tubes of perfectly cylindrical bore, but of different diameters, that of the wider being about 1·3 mm., and of the narrower about half as much. These two tubes are then united into a little U-tube (about 7 cm. long), which, after being partly filled with the experimental liquid, is hung in a wider vessel, at the bottom of which a little of the same liquid is kept boiling. From the difference of level of the liquid in these two connected capillary tubes, as measured at a temperature which must be very nearly the boiling-point, the surface-tension at that temperature is readily deduced, since the method of procedure involves the thorough wetting of the upper portion of the tube with condensed liquid.

In this manner Prof. Schiff has determined the surface-tension at the boiling-point of some sixty liquids, with a possible error which he estimates at 1·75 per cent. of the mean value—at the worst, 2·4 per cent. His results may be stated as follows:—

1. For isomeric liquids that are chemically comparable, the surface-tension at the boiling-point is the same (within the limits of observational error). The observations do indeed point in the case of isomers of one class to a fall in surface-tension with a fall in the boiling-point, while in another class there is a perceptible rise with a rise in the boiling-point, but these variations are within the limits of possible errors of observation.

2. The quantity which turns out to be that on which attention should be fixed is not the surface-tension itself, but the surface-tension divided by the molecular weight, a quantity to which the author gives a vivid significance by pointing out that, in the case of a capillary elevation against a vertical wall wetted by the liquid, it is proportional to and represents the *number of molecules raised above the free surface per unit length of the wall*; for, since the tension per unit length is equal to the weight of the total number of molecules lifted, this tension divided by the weight of each molecule gives the total number lifted.

To the surface-tension in milligrams per millimetre divided by the relative molecular weight (and multiplied for convenience by 1000), Prof. Schiff accordingly assigns the symbol N, and his results show that not only is this number N the same for isomeric substances (as is implied in the previous statement), but that it is often the same for liquids of very different chemical constitution. He then proceeds to examine the formulæ of such chemically different liquids which have the common property that N is the same, in the manner exemplified in the following illustration:—

"Taking all the different substances for which N is nearly 16, we find—

$$\text{Hexane, } C_6H_{14} \;\ldots\;\ldots\;\ldots\; N = 16{\cdot}1$$

$$\text{Xylol, ethyl-benzol, } C_8H_{10} \ldots\; N = \begin{cases} 16{\cdot}0 \\ 15{\cdot}9 \\ 15{\cdot}8 \\ 16{\cdot}2 \end{cases}$$

$$\text{With the formula } C_5H_{10}O_2 \;\ldots\; N = \begin{cases} 15{\cdot}8 \\ 15{\cdot}6 \\ 15{\cdot}6 \\ 15{\cdot}9 \\ 15{\cdot}7 \end{cases}$$

"This indicates that substances with the formulæ

$$C_6H_{14}, \qquad C_8H_{10}, \qquad C_5H_{10}O_2,$$

are, so far as concerns the value of the number (N) of molecules lifted, equivalent to each other.

"C_6H_{14} differs from C_8H_{10} in having C_2 less and H_4 more; accordingly, so far as concerns the constant N,

$$2C = 4H.$$

"C_8H_{10} differs from $C_5H_{10}O_2$ in having C_3 more and O_2 less, so that, with reference to the constant N,

$$3C = 2O."$$

In order to test whether these equivalences are accidental or not, he examines other series, for which N has respectively the value 10·5, 13, 27, &c., but always with the same result, so that he concludes that these equivalences are not chance coincidences, but that *it is really possible to replace a certain number of atoms of one kind by a certain number of another kind without producing in the value of* N *an alteration which comes within the limits of precise observation.*

From the equivalences $2C = 4H$ and $3C = 2O$
it follows that $C = 2H$
and $O = 3H$,
while from a similar examination of liquids containing chlorine he deduces $Cl = 7H$.

These equivalences enable him to write down what may be called the hydrogen equivalent, with respect to the value of the number N, of any compound of the four elements in question, *i.e.* the number of hydrogen atoms, which, if they existed as a molecule in the free state, would constitute a substance for which the value of N at the boiling-point would be the same as for the original substance. Thus, selecting a few substances whose hydrogen equivalents are tolerably evenly distributed over the range that he has examined, he obtains the following table:—

	H	N
CH_4O	$= H_9$	59·8
C_2H_6O	$= H_{13}$	38·4
C_3H_8O	$= H_{17}$	29·0
$C_3H_6O_2$	$= H_{18}$	27·0
$C_4H_8O_2$	$= H_{22}$	20·4
C_8H_{10}	$= H_{26}$	16·1
C_9H_{12}	$= H_{30}$	13·1
C_8H_{18}	$= H_{34}$	10·5
$C_8H_{16}O_2$	$= H_{38}$ ...	8·7
$C_{10}H_{22}$	$= H_{42}$ ...	7·7

From these observations as data, a curve is easily drawn of which the ordinates are proportional to the number of atoms in the hydrogen equivalent and the abscissæ to the corresponding value of N; and it is remarkable that the curve so drawn is of equable curvature, and corresponds equally well, not only to the selected data from which it is plotted, but also to all the other observed values of N, so that by transforming the molecular formula of any liquid into its hydrogen equivalent we can at once find, by reference to the curve, the value of N for the substance, and, by multiplying this by $\frac{\text{mol. weight}}{1000}$, we obtain the surface-tension at the boiling-point.

There are only three liquids for which Prof. Schiff notices that the value of N, as calculated from the curve, differs markedly from the observed value. These are—

Amylene (C_5H_{10}), for which	N (obsd.)	= 22, and	N (calcd.)	= 23·4
Diallyl (C_6H_{10})	,, ,,	= 18·4	,,	= 20·5
Ethylene-chloride ($C_2H_4Cl_2$)	,,	= 24·6	,,	= 20·5

In the first case the disagreement is explained by the presence of impurity; in the second, impurity is very possibly the cause; while in the third it is possible that the equation $Cl = H_7$ is not applicable to substances in whose formula more than a single carbon atom is represented, a point which the author hopes to clear up by further investigation. We observe, however, that to these disagreements should be added the case of ethyl-isobutyrate ($C_6H_{12}O_2$), for which N as given by the curve is 13·1, while the observed value was 12·3, a deviation of 7·5 per cent. On this the author makes no remark.

We will venture here to call attention also to a slight error that pervades all Prof. Schiff's results. We refer to the manner in which he corrects for the meniscus. The importance of this correction is in these measures very considerable, since the total elevation observed is always less than 10 mm. and sometimes less than 5 mm., and the correction is sometimes as much as . per cent. of the whole. Prof. Schiff, rejecting as insufficiently accurate Laplace's correction, which is based on the assumption that the surface of the meniscus may be regarded as that of a hemisphere of the same radius as the tube, and which consists therefore in adding to the observed height one-third of this radius, prefers to measure the height of the meniscus directly and to take as the correction one-third of the arithmetical mean between the observed height and the radius of the tube. In doing this he assumes that the surface may be regarded as that of a sphere of radius very appreciably greater than that of the tube, and gives a diagram in which it is so represented; but if this assumption or representation were correct, the laws of capillary tubes would be very different from what they are; moreover, according to theory, the form of the meniscus, and therefore the correction, must always be the same for liquids with the same capillary elevation; but Prof. Schiff's correction, based on the direct measurement of the meniscus, varies very considerably for elevations that are almost identical, which shows that the measures of the meniscus are not to be relied on: thus in the case of ethyl-toluol (para) (C_9H_{12}) the elevation is ·603 cm., and the correction ·013 cm., while for isobutyl-formiate ($C_5H_{10}O_2$) the elevation is ·599 cm., but the correction ·008 c.m., and in many cases one of two liquids which must theoretically have the greater correction has in point of fact the smaller. In order to see how far the empirical correction was at fault, we have selected one of Prof. Schiff's measures in which the elevation has about its mean value, and have calculated for comparison the correction of Hagen and Desains, which is based on the very approximately accurate assumption that the meniscus may be regarded as an oblate spheroid, and which is said to have been verified (? in the case of water) for tubes whose diameter attained as much as 4·6 mm. The following is the result:—

			mm.
Propyl Formiate:	observed elevation	=	6·45
,, ,,	Laplace's correction	=	− 0·1046
,, ,,	Hagen and Desains' correction	=	− 0·102
,, ,,	Schiff's correction	=	− 0·07

Corrected value (Schiff) 6·38; (Hagen and Desains), 6·348 mm.

It will thus be seen that an error of about ½ per cent. in the value of the surface-tension has entered into the result on this occasion, and that more has been lost than gained by substituting the empirical correction for that of Laplace; in some cases the error will be rather greater.

The importance in molecular physics of the step which Prof. Schiff has taken cannot easily be overrated. If it were only that he had found that isomeric substances have the same surface-tension at the boiling-point, that alone would have been a fact of great importance in reference to the interpretation of what we are accustomed to call the internal vapour-tension in a liquid; but in the system of absolute atomic equivalences with respect to surface-tension, and the knowledge of the manner in which the surface-tension varies with variations of the atomic equivalent, he has given to the physicist now for the first time most important data for correlating the surface-tension with the molecular actions existing expectively in the mass of the liquid and in the vapour above it.

A. M. W.

RESEARCHES ON THE ORIGIN AND LIFE-HISTORIES OF THE LEAST AND LOWEST LIVING THINGS[1]

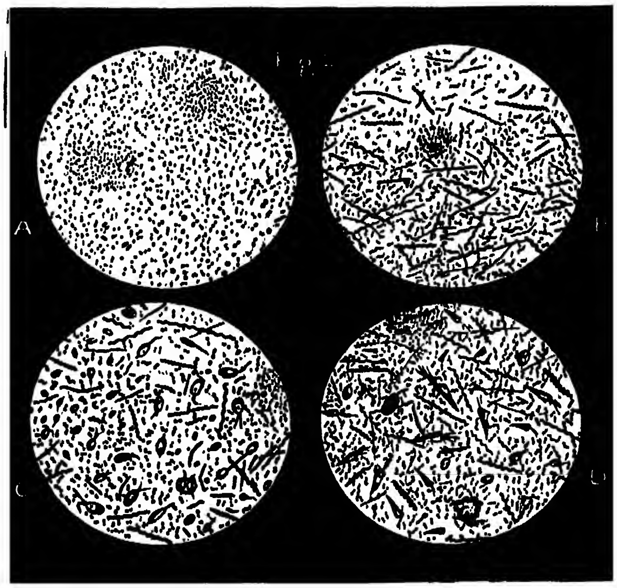
TO all who have familiarised themselves, even cursorily, with modern scientific knowledge, it is well known that the mind encounters the *infinite* in the contemplation of minute, as well as in the study of vast natural phenomena. The farthest limit we have reached, with the most gigantic standard of measurement we could well employ, in gauging the greatness of the universe, only leaves us with an overwhelming consciousness of the awful greatness—the abyss of the infinite—that lies beyond, and which our minds can never measure. The indefinite has a limit somewhere; but it is not the indefinite, it is the measureless, the infinite, that vast extension forces upon our minds. In like manner, the immeasurable in minuteness is an inevitable mental sequence from the facts and phenomena revealed to us by a study of the *minute* in nature. The practical divisibility of matter disclosed by modern physics may well arrest and astonish us. But biology, the science which investigates the phenomena of all living things, is in this matter no whit behind. The most universally diffused organism in nature, the least in size with which we are definitely acquainted, is so small that fifty millions of them could lie together in the one-hundredth of an inch square. Yet these definite living things have the power of locomotion, of ingestion, of assimilation, of excretion, and of enormous multiplication, and the material of which the inconceivably minute living speck is made, is a highly complex chemical compound. We dare not attempt a conception of the minuteness of the ultimate atoms that compose the several simple elements that thus mysteriously combine to form the complex substance and properties of this least and lowliest living thing. But if we could even measure these, as a mental necessity, we are urged indefinitely on to a minuteness without conceivable limit, in effect, a minuteness that is beyond all finite measure or conception. So that, as modern physics and optics have enabled us not to conceive merely, but to actually realise, the vastness of spatial extension, side by side

[1] By Rev. W. H. Dallinger, LL.D., F.R.S., F.L.S., Pres. R. M. S.

with subtle tenuity and extreme divisibility of matter, so the labour, enthusiasm, and perseverance of thirty years, stimulated by the insight of a rare and master mind, and aided by lenses of steadily advancing perfection, has enabled the student of life-forms not simply to become possessed of an inconceivably broader, deeper, and truer knowledge of the great world of visible life, of which he himself is a factor; but also to open up and penetrate into a world of minute living things so ultimately little that we cannot adequately conceive them, which are, nevertheless, perfect in their adaptations and wonderful in their histories. These organisms, whilst they are the least, are also the lowliest in Nature, and are to our present capacity totally devoid of what is known as organic structure, even when scrutinised with our most powerful and perfect lenses. Now these organisms lie on the very verge and margin of the vast area of what we know as living. They possess the essential properties of life, but in their most initial state. And their numberless billions, springing every moment into existence wherever putrescence appeared, led to the question, "How do they originate?" Do they spring up *de novo* from the highest point on the area of *not-life*, which they touch? Are they, in short, the direct product of some yet uncorrelated force in nature, changing the dead, the unorganised, the not-living into definite forms of life? Now this is a profound question, and that it is a difficult one there can be no doubt. But that it is a question for our laboratories is certain. And after careful and prolonged experiment and research the legitimate question to be asked is, Do we find that in our laboratories and in the observed processes of Nature now, that the not-living can be, without the intervention of living things, changed into that which lives?

To that question the vast majority of practical biologists answer without hesitancy, *No*, we have no facts to justify such a conclusion. Prof. Huxley shall represent them. He says, "The properties of living matter distinguish it absolutely from all other kinds of things," and, he continues, "the present state of our knowledge furnishes us with no link between the living and the not-living." Now let us carefully remember that the great doctrine of Charles Darwin has furnished biology with a magnificent generalisation: one indeed which stands upon so broad a basis that great masses of detail and many needful interlocking facts are, of necessity, relegated to the quiet workers of the present, and the earnest labourers of the years to come. But it is a doctrine which cannot be shaken. The constant and universal action of variation, the struggle for existence, and the "survival of the fittest," few who are competent to grasp will have the temerity to doubt. And to many, that which lies within it as a doctrine, and forms the fibre of its fabric, is the existence of a continuity, an unbroken stream of unity running from the base to the apex of the entire organic series. The plant and the animal, the lowliest organised and the most complex, the minutest and the largest, are related to each other so as to constitute one majestic organic whole. Now to this splendid continuity practical biology presents no adverse fact. All our most recent and most accurate knowledge confirms it. But *the* question is, Does this continuity terminate now in the living series, and is there then a break—a sharp, clear discontinuity, and beyond, another realm immeasurably less endowed, known as the realm of not-life? or, Does what has been taken for the clear-cut boundary of the vital area, when more deeply searched, reveal the presence of a force at present unknown, which changes not-living into the living, and thus makes all nature an unbroken sequence and a continuous whole? That this is a great question, a question involving large issues, will be seen by all who have familiarised themselves with the thought and fact of our times. But we must treat it purely as a question of science; it is not a question of *how* life *first* appeared upon the earth, it is only a question of whether there is any natural force *now* at work building not-living matter into living forms. Nor have we to determine whether or not, in the indefinite past, the not-vital elements on the earth, at some point of their highest activity, were endowed with, or became possessed of, the properties of life.

On that subject there is no doubt. The elements that compose protoplasm—the physical basis of all living things—are the familiar elements of the world without life. The mystery of life is not in the elements that compose the vital stuff. We know them all, we know their properties. The mystery consists *solely* in *how* these elements can be so combined as *to acquire* the transcendent properties of life. Moreover, to the investigator it is not a question of *by what means* matter dead—without the shimmer of a vital quality—became either slowly or suddenly possessed of the properties of life. Enough for us to know that whatever the power that wrought the change, that power was competent, as the issue proves. But that which calm and patient research has to determine is whether matter demonstrably *not living* can be, without the aid of organisms already living, endowed with the properties of life. Judged of hastily, and apart from the facts, it may appear to some minds that an origin of life from not-life, by sheer physical law, would be a great philosophical gain; an indefinitely strong support of the doctrine of evolution. If this were so, and, indeed, so far as it is believed to be so, it would speak and does speak volumes in favour of the spirit of science pervading our age. For although the vast majority of biologists in Europe and America accept the doctrine of evolution, they are almost unanimous in their refusal to accept as in any sense competent the reputed evidence of "spontaneous generation"; which demonstrates, at least, that what is sought by our leaders in science is not the mere support of hypotheses, cherished though they may be: but the truth, the uncoloured truth, from nature. But it must be remembered that the present existence of what has been called "spontaneous generation," the origin of life *de novo* to-day, by physical law, is by no means required by the doctrine of evolution. Prof. Huxley, for example, says, "If all living beings have been evolved from pre-existing forms of life, it is enough that a single particle of protoplasm should *once* have



appeared upon the globe, as the result of no matter what agency; any further independent formation of protoplasm would be sheer waste." And why? we may ask. Because one of the most marvellous and unique properties of protoplasm, and the living forms built out of it, *is the power* to multiply indefinitely and for ever! What need, then, of spontaneous generation? It is certainly true that evidence has been adduced purporting to support, if not establish, the origin in dead matter of the least and lowest forms of life. But it evinces no prejudice to say that it is inefficient. For a moment study the facts. The organisms which were used to test the point at issue were those known as *Septic*. The vast majority of these are inexpressibly minute. The smallest of them, indeed, is so small that, as I have said, fifty millions of them, if laid in order, would only fill the one-hundredth part of a cubic inch. Many are relatively larger, but all are supremely minute. Now, these organisms are universally present in enormous numbers, and ever rapidly increasing in all moist putrefactions over the surface of the globe.

Take an illustration prepared for the purpose and taken direct from nature. A vessel of pure drinking water was taken during the month of July at a temperature of 65° F., and into it was dropped a few shreds of fish muscle and brain. It was left uncovered for twelve hours; at the end of that time a small blunt rod was inserted in the now somewhat opalescent water, and a minute drop taken out and properly placed on the

microscope, and, with a lens just competent to reveal the minutest objects, examined. The field of view presented is seen in Fig. 1, A. But—with the exception of the dense masses which are known as zoogloea or bacteria, fused together in living glue—the whole field was teeming with action. Each minute organism gyrating in its own path, and darting at every visible point. The same fluid was now left for sixteen hours, and once more a minute drop was taken and examined with the same lens as before. The field presented to the eye is depicted in Fig. 1, B, where it is visible that whilst the original organism persists yet a new organism has arisen in and invaded the fluid. It is a relatively long and beautiful spiral form, and now the movement in the field is entrancing. The original organism darts with its vigour and grace, and rebounds in all directions. But the spiral forms revolving on their axes glide like a flight of swallows over the ample area of their little sea. Ten hours more elapsed and, without change of circumstances, another drop was taken from the now palpably putrescent fluid. The result of examination is given in Fig. 1, C, where it will be seen that the first organism is still abundant, the spiral organism is still present and active, but a new and oval form, not a bacterium, but a *monad*, has appeared. And now the intensity of action and beauty of movement throughout the field utterly defy description, gyrating, darting, spinning, wheeling, rebounding with the swiftness of the grayling and the beauty of the bird. Finally, at the end of another eight to sixteen hours, a final "dip" was taken from the fluid, and under the same lens it presented as a field what is seen in Fig. 1, D, where the largest of the putrefactive organisms has appeared and has even more intense and more varied movements than the others. Now the question before us is, "How did these organisms arise?" The water was pure; they were not discoverable in the fresh muscle of fish. Yet in a dozen hours the vessel of water is peopled with hosts of individual forms which no mathematics could number! How did they arise? from universally diffused eggs? or from the direct physical change of dead matter into living forms? Twelve years ago the life-histories of these forms were unknown. We did not know biologically how they developed. And yet with this great deficiency it was considered by some that their mode of origin could be determined by heat experiments on the adult forms. Roughly the method was this. It was assumed that nothing vital could resist the boiling point of water. Fluids, then, containing full-grown organisms in enormous multitudes, chiefly bacteria, were placed in flasks, and boiled for from five to ten minutes. While they were boiling the necks of the flasks were hermetically closed; and the flask was allowed to remain unopened for various periods. The reasoning was: "Boiling has killed all forms of vitality *in* the flask; by the hermetical sealing nothing living can gain subsequent access to the fluid; therefore, if living organisms do appear when the flask is opened, they must have arisen in the dead matter *de novo* by spontaneous generation, but if they do never so arise the probability is that they originate in spores or eggs."

Now it must be observed concerning this method of inquiry that it could never be final: it is incompetent by deficiency. Its results could never be exhaustive until the life-histories of the organisms involved were known. And further: although it is a legitimate method of research for partial results, and was of necessity employed, yet it requires precise and accurate manipulation. A thousand possible errors surround it. It can only yield scientific results in the hands of a master in physical experiment. And we find that when it has secured the requisite skill, as in the hands of Prof. Tyndall, for example, the result has been the irresistible deduction that living things have never been seen to originate in not-living matter. Then the ground is cleared for the strictly biological inquiry, How do they originate? To answer that question we must study the life-histories of the minutest forms with the same continuity and thoroughness with which we study the development of a crayfish or a butterfly. The difficulty in the way of this is the extreme minuteness of the organisms. We require powerful and perfect lenses for the work. Happily during the last fifteen years the improvement in the structure of the most powerful lenses has been great indeed. Prior to this time there were English lenses that amplified enormously. But an enlargement of the image of an object avails nothing, if there be no concurrent disclosure of detail. Little is gained by expanding the image of an object from the ten-thousandth of an inch to an inch, if there be not an equivalent revelation of hidden details. It is in this revealing quality, which I shall call *magnification* as distinct from *amplification*, that our recent lenses so brilliantly excel. It is not easy to convey to those unfamiliar with objects of extreme minuteness a correct idea of what this power is. But at the risk of extreme simplicity, and to make the higher reaches of my subject intelligible to all, I would fain make this plain.

But to do so I must begin with familiar objects, objects used solely to convey good relative ideas of minute dimension. I begin with small objects with the actual size of which you are familiar. All of us have taken a naked-eye view of the sting of the wasp or honey-bee; we have a due conception of its size. This is the scabbard or sheath, which the naked eye sees.[1] Within this are two blades, terminating in barbed points. The point of the scabbard more highly magnified is presented, showing the inclosed barbs. One of the barbs, looked at on the barbed edge, is also seen. Now these two barbed stings are tubes, with an opening in the end of the barb. Each is connected with the tube of the sac C. This is a reservoir of poison, and D is the gland by which it is secreted. Now I present this to you, not for its own sake, but simply for the comparison, a comparison which struck the earliest microscopists. Here is the scabbard carefully rendered. One of the stings is protruded below its point, as in the act of stinging: the other is free to show its form. Now the actual length of this scabbard in nature was the *one-thirtieth* of an inch. I have taken the point C of a fine cambric sewing needle, and broken it off to slightly less than the one-thirtieth of an inch, and magnified it as the sting is magnified. Now here we obtain an instance of what I mean by magnification. The needle-point is not merely bigger, unsuspected details start into view. The sting is not simply enlarged, but all its structure is revealed. Nor can we fail to note that the *finish* of art differs from that of Nature. The homogeneous gloss of the needle disappears under the fierce scrutiny of the lens, and its delicate point becomes furrowed and riven. But Nature's finish reveals no flaw, it remains perfect to the last.

We may readily amplify this. The butterflies and moths of our native lands we all know; most of us have seen their minute eggs. Many are quite visible to the unaided eye; others are extremely minute. A gives the egg of the Small White Butterfly,[2] B that of the Small Tortoiseshell, C that of the Waved Umber Moth, D that of the Thorn Moth, E that of the Shark Moth, at F we have the delicate egg of the Small Emerald Butterfly, and at G an American Skipper, and finally at H the egg of a moth known as Mania Maura. In all this you see a delicacy of symmetry, structure and carving, not accessible to the eye, but clearly unfolded. We may, from our general knowledge, form a correct notion of the average relation in size existing between butterflies and their eggs; so that we can compare. Now there is a group of extremely minute insect-like forms that are the parasites of birds. Many of them are just plainly visible to the naked eye, others are too minute to be clearly seen, and others yet again wholly elude the unaided sight. The c Epizoa generally lodge themselves in various parts of the plumage of birds; and almost every group of birds becomes the host of some specific or varietal form with distinct adaptations. There is here seen a parasite that secretes itself in the inner feathers of the peacock, this is a form that attacks the jay, and here is one that secretes itself beneath the plumage of the partridge.

Now these minute creatures also deposit eggs. They are placed with wonderful instinct in the part of the plumage and the part of the feather which will most conserve their safety; and they are either glued or fixed by their shape or by their spine in the position in which they shall be hatched. I show here a group of the eggs of these minute creatures. I need not call your attention to their beauty; it is palpable. But I am fain to show you that, subtle and refined as that beauty is, it is clearly brought out. The flower-like beauty of the egg of the peacock's parasite, the delicate symmetry and subtle carving of the others simply entrance an observer. Note then that it is not merely *enlarged* specks of form that we are beholding, but such true magnifications of the objects as bring out all their subtlest details. And it is *this* quality that must characterise our most powerful lenses. I am almost compelled to note in passing that the *beauty* of these delicate and minute objects must not be considered *an end*—a purpose—in Nature. It is not so. The form is what it is because it *must be* so to serve the end for which the egg is formed. There is not a superfluous spine,

[1] A magnified image of the bee's sting was projected on the screen.

[2] A series of the eggs of butterflies were then shown, as were the objects successively referred to but not here reproduced.

not a useless petal in the floral egg, not an unneeded line of chasing in the decorated shell. It is shaped beautifully because its shape is needed. In short, it is Nature's method; the identification of beauty and use. But to resume. We may at this point continue our illustrations of the analytical power of moderate lenses by a beautiful instance. We are indebted to Albert Michael of the Linnean Society of England for a masterly treatise on a group of Acari, or *Mites*, known as the *Oribatidæ*. Many of these he has discovered. The one before you is a full grown Nymph, of what is known as a *palmicinctum*. It is deeply interesting as a form; but for us its interest is that it is minute, being only a millimetre in length. But it repeatedly casts the dorsal skin of the abdomen. Each skin is bordered by a row of exquisite scales; and then successive rows of these scales persist, forming a protection to the entire organism. Mark then that we not only reveal the general form of the Nymph, but the lens reveals the true structure of the scales, not enlargement merely, but detail. The egg of the organism, still more magnified, is also seen.

To vary our examples and still progress. We all know the appearance and structure of chalk. The minute Foraminifera have, by their accumulated tests, mainly built up its enormous masses. But there is another chalk known as Barbadoes earth; it is siliceous, and is ultimately composed of minute and beautiful skeletons such as those which, enormously magnified, you now see. These were the glassy envelopes which protected the living speck that dwelt within and built it. They are the minutest of the Radiolaria, which peopled in inconceivable multitudes the Tertiary oceans; and, as they died, their minute skeletons fell down in a continuous rain upon the ocean bed, and became cemented into solid rock, which geologic action has brought to the surface in Barbadoes, and many other parts of the earth. If a piece of this earth, the size of a bean, be boiled in dilute acid and washed, it will fall into powder, the ultimate grains of which are such forms as these which you see. The one before you is an instance of exquisite refinement of detail. The form from which the drawing of the magnified image was made was extremely small—a mere white speck in the strongest light upon a black ground. But you observe it is not a speck of form merely enlarged. It is not merely beauty of outline made bigger. But there is—as in the delicate group you now see—a perfect opening up of otherwise absolutely invisible details. We may strengthen this evidence in favour of the analytical power of our higher lenses, by one more *familiar* example, and then advance to the most striking illustration of this power which our most perfect and powerful lenses can afford. I fear that it may be taking too much for granted to assume that every one in an audience like this has seen a human flea! Most, however, will have a dim recollection or suggestive instinct as to its size in nature. Nothing striking is revealed by this amount of magnification excepting the existence of breathing pores, or spiracles along the scale armour of its body. But there is a trace of structure in the terminal ring of the exoskeleton which we cannot clearly define, and of which we may desire to know more. This can be done only by the use of far higher powers.

To effect this, we must carefully cut off this delicate structure, and so prepare it that we may employ upon it the first of a series of our highest powers. The result of that examination is given here.[1] You see that the whole organ has a distinct form and border, and that its carefully carved surface gives origin to wheel-like areolæ which form the bases of delicate hairs. The function of this organ is really unknown. It is known from its position as the *pygidium*; and from the extreme sensitiveness of the hairs to the slightest aërial movement may be a tactile organ warning of the approach of enemies, the eyes have no power to see. But we have not yet reached the ultimate accessible structure of this organ. If we place a portion of the surface under one of the finest of our most powerful lenses, this will be the result.[2] Now, without discussing the real optical or anatomical value of this result as it stands, what I desire to remind you of is (1) the natural size of the flea; (2) the increase of knowledge gained by its general enlargement; (3) the relation in size between the flea and its pygidium; and (4) the manner in which our lenses reveal its structure, not merely amplify its form. Now with these simple and yet needful preliminaries you will be able to follow me in a careful study of the least, the very lowliest and smallest, of all living things. It lies on the very verge of our present powers of optical aid, and what we know concerning it will convince you that we are prepared with competent skill to attack the problem of the life-histories of the smallest living forms. The group to which the subject of our present study belongs is the Bacteria. They are primarily staff-like organisms of extreme minuteness, but may be straight, or bent, or curved, or spiral, or twisted rods. This entire projection is drawn on glass, with *camera lucida*, each object being magnified 2000 diams., that is to say, four millions of times in area. Yet the entire drawing is made upon an area of not quite three inches in diameter and afterwards projected here. The objects therefore are all equally magnified, and their relative sizes may be seen. The giant of the series is known as *Spirillum volutans*; and you will see that the representative species given become less and less in size until we reach the smallest of all the definite forms and known to science as *Bacterium termo*.

Now within given limits this organism varies in size, but if a fair average be taken its size is such that 50,000,000 laid in order would only fill the one-hundredth of a cubic inch. Now the majority of these forms *move* with rapidity and grace in the fluids they inhabit. But how? by what means? By looking at the largest form of this group you will see that it is provided with two delicate fibres, one at each end. Ehrenberg and others strongly suspected their existence, and we were enabled, with more perfect lenses, to *demonstrate* their presence some twelve years ago. They are actually the swimming organs of this Spirillum. The fluid is lashed rhythmically by these fibres, and a spiral movement of the utmost grace results. Then do the intermediate forms that move also possess these flagella? and does this least form in nature, viz. *Bacterium termo*, accomplish its bounding and rebounding movements in the same way? Yes! by a series of resolute efforts, in using a new battery of lenses—the finest that at that time had ever been put into the hands of man—I was enabled to show in succession that each motile form of Bacterium up to *B. lineola* accomplished its movements by fibres or flagella; and that in the act of self-division, constantly taking place, a new fibre was drawn out for each half before separation.

(To be continued.)

[2] An illustration of the pygidium structure seen with 1/35th immersion was given

THE PERIPATETIC METHOD OF INSTRUCTION IN SCIENCE AND ITS DEVELOPMENT[1]

THE object of this paper is to plead for the introduction of science as a part of the system of ordinary education in all public elementary schools, and to describe the method by which alone, in the opinion of the writer, it is possible that this should be accomplished. There is a general consensus of opinion that a far larger place than has hitherto been allowed in England should be assigned to science in our national system of education, as well as in our grammar-schools and Universities; but no strong conviction yet exists that a certain amount of strict and definite scientific training should be given to all the scholars in our public elementary schools as soon as they are prepared to receive it, which is practically found to be after they have passed the fourth standard. The extent of this claim for the introduction of science as a part of the ordinary curriculum of a public elementary school must be noted, in order that the worth and importance of the proposed method for securing thoroughly effective teaching may be understood.

The provision of special scholarships for those who possess exceptional intellectual power—admirable and necessary as this is—does not meet the broad claim I make. To furnish stages in the ladder by which a lad of mark, endowed with "five talents," may climb from the elementary school to the science college, is only to offer to the children of the poor opportunities to which they are justly entitled by virtue of the fact that genius, like truth, can neither be bought or sold, and is bestowed upon men entirely apart from any considerations connected with social rank and circumstances. But scholars of average ability, those who have no special endowments qualifying them for exceptional careers, ought not to be kept in ignorance of the fixed laws and the majestic marvels of the world in which they will have to labour, or to be deprived of the practical guidance, the intellectual interests, and the protection against coarse and degrading tastes, which scientific training is capable of bestowing upon

[1] Paper read at the Social Science Congress, September 22, by Henry W. Crosskey, LL.D., Chairman of the School Management Committee of the Birmingham School Board.

their lives. Only a few can rise to eminence; and it is an unmitigated misfortune for any lad to be encouraged to trust to his intellectual powers for his daily bread, unless he has a fair chance of becoming eminent; but all may possess the scientific knowledge which will give dignity to their daily toil; and the workshop itself may be ennobled.

Neither does the establishment of higher-grade Board schools, in which scientific instruction is given, meet the necessities of the case. The vexed and complicated questions involved in the general organisation of the very miscellaneous collection of schools now existing in England do not fall within the scope of this paper; but I find that many members of School Boards believe that all that is required for scientific instruction will be done when higher grade Board schools are opened; and, by means of examinations and scholarships, admission is brought within reach of a certain number of poor children unable to pay the fee.

Now, the grading of schools must educationally depend upon the time which the scholars can be expected to devote to education; and each grade of schools ought to have a curriculum, determined in its extent and balanced in its parts, according to the number of years which can be spent upon it. The public elementary school should furnish the completest possible education for those who can remain at school until the age of fourteen or fifteen; the higher-grade schools, which properly belong to the secondary system, should be adapted to the wants of scholars who can be retained a year or two longer. The higher-grade school cannot therefore supply the place of the public elementary school to the poor man, who is obliged to send his children to work at a comparatively early age; the number of subjects taught, and the relative number of hours given to them, will not be balanced in a way to suit his requirements.

My contention is that science ought not to be omitted from the educational training of the poorest of our people. The daily concern of the lives of the poor is with forces and materials upon which science throws the strongest light. Their work is bound up with scientific laws. Want of knowledge often means bad work or want of work; and even the spread of pestilence, disease, and death.

The establishment of higher-grade Board schools ought not, therefore, under any circumstances, to be permitted to lower the standard of education in public elementary schools. I speak emphatically on this point, because I believe that the working men of this country will need to take the most watchful heed lest they should be deprived of the education all their children are capable of receiving by the relegation of scientific subjects to schools placed beyond their reach by high fees, mitigated by only a small proportion of free scholarships.

Neither will the opening of technical schools suffice for the scientific instruction of our people. Technical schools cannot do their proper work if their students have had no preliminary training, and are unfamiliar with at least the elementary principles of physics. Lads who have grown into young men without being carried through any systematic and experimental course of scientific instruction will find it almost impossible, after they have left school, to prepare themselves properly for taking advantage of technical colleges, especially when, as among the working classes, their evenings only are at their own disposal.

In order that science may be effectively taught in public elementary schools, the following conditions must be observed:—

1. *It must be taught experimentally.*—Actual demonstration must accompany the lessons at every stage. At no point at which an experiment is possible must it be omitted. The minds of young lads of the type of those attending public elementary schools will be opened and enlarged by experimental demonstrations, but they will not be reached in any other way. Scholars may be able to pass examinations by getting up text-books; but unless they are made experimentally familiar with the principles of the science they are studying, their knowledge will hang as a dead weight upon their minds, impeding rather than quickening their intellectual activity. Those who have witnessed, as I have often done, the effect of an experimental lesson in science upon large classes of children, often drawn from the poorest of the poor, will not think this insistence upon a plenitude of experiments exaggerated. The demonstration thoroughly awakens their minds; their eyes glisten; there is a long-drawn "Ha" when the result accords with the theory which the teacher has expounded; and questions will soon show that they are not merely wondering at a conjuring trick, but that a new world, hidden within the world of machinery with which they are familiar through the daily avocations of their parents, is being revealed to them.

2. Science must not only be taught experimentally, but systematically and continuously. The "getting up" of some branch of science during three or four months as a "specific subject" for examination is of little use. "Passes" may be won; but no scientific training will be given.

From these considerations it directly follows that special science demonstrators must be appointed if our scholars are to receive a scientific training of any worth. It may be asked, cannot the work be done by one of the ordinary masters of the school? I am bound to reply that in my opinion—an opinion not lightly formed, but based on observations extending over a not inconsiderable area—it is absolutely impossible to obtain any training which can be called scientific, and prove of practical value, for the scholars of our public elementary schools, without the appointment of special science demonstrators.

In the first place, no man can be a good science demonstrator who does not devote to the work the greater part of his daily life. To perform experiments well is as much an art to be acquired by continuous study and practice as playing the piano. Fertility of resource, quickness of eye and hand, steadiness of mind, keenness of observation, are qualities essential to the demonstrator, which cannot be acquired without culture or retained without constant employment. The master of a school has many subjects to teach and many duties to discharge. He cannot, by any possibility, give any sufficient proportion of his time to the art and practice of scientific demonstration.

It may be said that an expert cannot be required for scholars of the age of those attending public elementary schools, and that any experiments they can understand can be easily performed by any ordinary teacher. Those who have studied any branch of physical science, however, will, I think, agree with me that no science can be well taught except by a man who has had a special scientific training; and that the simplest experiments are best performed and made the most intelligible by those capable of carrying on the more recondite and difficult investigations.

It is a great mistake to imagine that it is a light and easy matter to experiment before a class of scholars, such as those found in our Board schools. They are on the alert for any mistake; they are ready to raise the most curious and subtle doubts, and to ask the most perplexing questions. The only man capable of dealing with such a class of scholars is a man they are compelled to recognise as a master of the science he is teaching.

In the second place, even if the head master of a public elementary school were a scientific expert and managed to keep abreast with the advance of the scientific knowledge of his day, he would find it completely out of his power to act as a science demonstrator and to conduct the general work of his school. The preparation necessary for giving a good science lesson cannot be made without a larger expenditure of time than the proper management of his school will leave at his disposal. The mechanical arrangements for experiments often demand long-continued and anxious watchfulness and care. Every experiment ought to be tried over, before it is performed in the class, to avoid the risk of failure. The proper selection of experiments, as well as their performance, is in itself an art.

For the teaching of science in public elementary schools, therefore, these things are necessary: (1) sufficient apparatus, and of course a laboratory in which experiments can be prepared; and (2) a staff of special science demonstrators.

The expense of providing apparatus, building a laboratory, and supporting a science demonstrator at every single school in town and country, would be as enormous as unnecessary. By the general adoption, however, of what is known as the "peripatetic" method of instruction, all difficulties can be solved; and science can be effectively taught in every public elementary school. I do not think, indeed, that any other satisfactory method can be devised by which the whole of our elementary schools can be reached and the services of those trained scientific men, whose teaching of the elementary principles of science is alone to be relied upon, be secured for the great mass of our people. The peripatetic method has been adopted in Liverpool and Birmingham, and as I can testify so far as Birmingham is concerned, the results have been as satisfactory as remarkable.

The chief characteristics of this method are extremely simple:—

I. As regards "plant," it involves (1) the building of a laboratory in some central position; (2) the purchase of a stock of apparatus; (3) the provision of a small hand-cart by which boxes containing apparatus can be readily carried from school to school.

II. A special science demonstrator is appointed, with such assistants as the number of schools to be dealt with may require.

III. The duties of the science demonstrator are (1) to prepare a scheme of lessons and arrange the experiments for their illustration: in Birmingham, in the boys' departments, mechanics is taken as a "specific subject," and in some schools magnetism and electricity are added; in the girls' departments, domestic economy is taken, and animal physiology is in some cases added; (2) to visit the schools in succession, and give at each school a lesson profusely illustrated by experiments, the requisite apparatus being brought by the hand-cart from the central laboratory.

IV. The regular staff of the school assists the demonstrator, and is assisted by him in the following ways:—

(1) A teacher on the staff of the school is present at every demonstration, and is thus prepared to enforce and continue its lessons in the intervals elapsing between the demonstrator's visits.

(2) The scholars have opportunity given them during school hours to write answers to questions set by the demonstrator, who examines their papers.

In Birmingham a "demonstration" is given in each department once a fortnight. It would be, however, a great improvement if the demonstrator or one of his staff could visit each school once during every week. The science staff consists of a chief demonstrator (Mr. W. Jerome Harrison, F.G.S., whose services deserve the warmest acknowledgment), three assistant demonstrators, who assist in giving lessons at the schools, and a junior laboratory assistant. Two youths are employed to work the hand-cart. The whole amount of salary paid to this staff amounts to 750*l*. per annum.

Scientific instruction is given by this method in thirty boys' schools and thirty girls' schools, containing about 32,000 scholars, the numbers in the classes and the specific subjects taken being:—

Mechanics	2400	Boys
Magnetism and Electricity	300	,,
Domestic Economy	1800	Girls
Animal Physiology	100	,,

Objections may possibly be taken to this system in the following directions:—

I. *Its cost.*—It being granted, however, that thorough and systematic scientific instruction ought to be introduced into elementary schools, the peripatetic method is the very cheapest that can be devised. One set of apparatus serves for many schools, and one laboratory suffices for the preparation of the experiments. The services of the staff are utilised to the utmost; and the amount of salary to be charged against each school is trifling. Supposing twenty schools in a town or neighbouring villages to be grouped together, the system might be worked at a very slight expense to each. The investment of capital required would be less than 1000*l*., viz.:—

Building of Central Laboratory[1]	£700
Apparatus	300
	£1000

The annual working expenses would be—

Salaries of science demonstrator and assistant ...	£400
Waste of chemicals, renewal of apparatus, &c. ..	50
Expense of moving apparatus from laboratory to school	50
	£500

Ample provision could be made at this cost for twenty schools, each having accommodation for 300 or 400 children, *i.e.* each of the associated schools could obtain, for about 25*l*. a year, thoroughly good experimental instruction for all scholars who have passed the fourth standard.

II. It may be asked whether, in the short time that can be allowed for any specific subject, it is possible to obtain results of sufficient educational worth to justify the expenditure of labour, thought, and money I am advocating. As a reply to this objection, I can point without fear to the results actually attained in Birmingham; an hour to an hour and a half a week being all the time which has been spared for science, including the fortnightly demonstration, the recapitulation, and preparation of exercises. The teaching being experimental, an impression is made upon the minds of the scholars which can neither be equalled or measured by the effects of ordinary class teaching, lecturing, or book work. The scholars are induced to think, and read, and prepare models of machines and drawings out of school hours; and during school hours they are found to apply themselves with a will to their scientific exercises. Prof. Poynting (of Mason College) has examined a large number of boys competing for a scholarship, and reported to the Board that "the boys showed that they had seen and understood the experiments which they described, that they had been taught to reason for themselves upon them, and that they were not merely using forms of words which they had learned without attaching physical ideas to them." Specimens of the models made by the children, their drawings, a d examination papers, have been exhibited at the International Health Exhibition, of which the subjoined account is given in the *School Board Chronicle* (August 9, 1884):—"The cabinet of machines and models and copies of the science apparatus used by the demonstrators in their experiments is well worthy of a visit. It shows the extent and nature of the interest which the children take in this practical form of education. Most of the models have been made by the children at their homes, and often with very inferior tools. One lad has a copy of the Chinese windlass, another makes a little pile engine, and a third illustrates the inclined plane, a fourth the mariner's compass, and so on through a great variety of objects, until a very tolerable little collection of rough but serviceable apparatus has been brought. In cases extending the length of one of the walls of the room is a collection of specimen papers and drawings, prepared at the demonstrator's fortnightly examination of the results of his preceding lesson, and no further justification of the system than these papers can be needed."

In comparing these models and papers with others, it must be remembered that the Birmingham work was not done in any "higher-grade" institutions, with high fees and picked scholars, but indicates the kind of scientific training that may be given by the help of the peripatetic method in any public elementary school.

III. Great anxiety is felt by many lest the introduction of science into elementary schools should result in mere "cram" and a number of hard technical words be repeated by rote to be forgotten as soon as school is left. It is not unusual to hear a laugh raised by the quotation of some technical word from an examination paper, as though its use reduced the system to an absurdity. Scientific facts are, however, most clearly expressed in scientific language. Even young scholars gain by knowing the *right words* by which physical facts and laws are described and their intellects are bemuddled by vague expressions. The employment of scientific words is no proof of "cram." I admit, as a matter of course, that the attempt to teach science without demonstrating experimentally every fact and law, must result in cramming of the worst description; but *experimental teaching gives the death-blow to cram.*

IV. Will not, however, it is sometimes asked, the introduction of this system of scientific teaching interfere with the progress of the children in writing, reading, and arithmetic? Will not the elements of ordinary education be neglected because of the attention demanded for such scientific subjects as mechanics, magnetism, and electricity? On the contrary, it is found as a matter of fact, that the intellectual life of the school is quickened in every direction by the study of science. The scholars find that the "three R's" are not dull, dry, and abstract pursuits but keys to a world of new marvels and interests. The schools under the Birmingham Board in which there is the keenest interest in science are certain to prove the schools in which the ordinary work is best done. Since 1880, when the science demonstrator was first appointed, the percentage of passes in the "three R's" has steadily increased, as well as the number of passes in specific subjects.

Year		Number of passes in specific subjects	Percentage of passes in the "three R's"
1880		841	84·7
1881		1724	88·4
1882		3114	92·6
1883	New Code with higher requirements	3150	89·6

[1] The Birmingham laboratory cost (with fittings) 1450*l*., but it has a lecture-room and private room for demonstrator attached.

Various causes have, no doubt, contributed to this result; but the proof is positive that the introduction of science *has not interfered*, to say the least, with elementary education in the "three R's."

V. On the first introduction of the system there may be a certain amount of antagonistic feeling aroused amongst some head masters and mistresses. In Birmingham this was indeed to some small extent the case. Some head teachers feared that the demonstrator would prove a new inspector, who, having to discharge duties as a teacher, might unduly interfere with their own functions, and that some conflict of authority might occur. To the best of my knowledge, however, this feeling has entirely disappeared. The only complaints which I hear as Chairman of the School Management Committee, are when the experimental lessons are omitted at any school through any stress of examination work or accidental circumstance. The masters find that the science demonstrators render them valuable assistance and do a work which it is out of their own power to accomplish.

In order to apply the severest test to the peripatetic system, I applied to the head master of a large school, situated in one of the very poorest districts in Birmingham, and attended by children whose social surroundings are, as a rule, almost as unfavourable to intellectual development as they can possibly be. The school has accommodation for 416 boys, and an average attendance of about 350, 414 being sometimes present during the week.

The reply of the head master to my request that he would inform me of the results of the science teaching in his school, lifts the whole question out of the region of controversy.

Dartmouth Street Boys' Board School, Birmingham, September 9, 1884.

Rev. Sir,—In reply to yours of this morning, I beg to make the following remarks:—

The results from the science lessons given in this school are very gratifying. I have seen results in a variety of ways both in and out of school.

The interest taken in these lessons, both by parents and boys, is surprising. Many a mother has, to my frequent knowledge, inconvenienced herself in her domestic duties on certain days when we have sent word for her boy to be present, as the science demonstrator was expected that morning. The day is well remembered by most of them, and eagerly looked forward to. The attendance in the uppermost class is wonderfully increased on the mornings these lessons are given.

The results in other subjects in those standards where science is taught are none the less satisfactory. A greater intelligence and thought are quickly discovered when we are dealing with the other subjects.

Teachers are more encouraged when brighter material to work with is placed in their hands.

Other important subjects have impressed me very much, viz. the desire of the boys after leaving school to continue to study some science subject at some of our science classes.

Older brothers, too, have been induced to go to science classes through seeing the growth of knowledge in those much younger than themselves.

Many persons who have reason to come in contact with the boys after leaving school, have expressed themselves in tones of great regret that such instruction was not given when they attended school.

I remain, Rev. Sir,
Your obedient servant,
Rev. Dr. Crosskey. T. H. PURCELL

As a development of the systematic and experimental system of science training I have described—a system only rendered possible of adoption by the employment of the peripatetic method—a new kind of Board school has been opened in Birmingham, for the purpose of enabling the scientific work commenced in the elementary school to be continued by the more advanced scholars before they enter upon their respective employments in workshops and factories.

The arrangements of the peripatetic system will suffice until the sixth standard is passed; but special provision must be made for those lads who can remain a year or two longer at school, and whose future employments render the extension of their scientific training desirable. A large proportion of those who pass the sixth standard are obliged to earn their livings at once; for these various evening classes are available. But a certain number of working men can, by an effort, manage to exempt their children from toil, say for an extra two years.

The question therefore arises whether special provision cannot be made for scholars who must ultimately earn their living as working men, but whose parents can afford to keep them at school for two years after they have passed the sixth standard?

It is evident that for such scholars increased facilities for scientific study will have a peculiar, indeed almost an incalculable, importance.

They have been well grounded in the first principles of science and familiarised with the management of apparatus and the conduct of experiments during their school career. Their work in life will be largely increased, not only in pecuniary and mechanical, but in intellectual and moral value, by scientific knowledge.

To meet the wants of this class, a school has been opened as an experiment, in New Bridge Street, Birmingham, in premises belonging to the Chairman of the Board (Mr. George Dixon), who, at the cost of more than 2000*l.*, has adapted them for the purpose, and placed them rent free at the service of the Board.

The characteristics of this school are the following:—

I. It is especially intended for scholars who will have to become working men, but whose parents can keep them at school after they have passed the sixth standard, and the fee (3*d.* a week) is adapted to their means.

II. While a seventh standard school under the Code, the instruction given is largely scientific and technical; and a special staff of trained scientific men has been appointed. There is a special master for chemistry and metallurgy; another master for mechanics and physics; a drawing master; and a mathematical master; a highly qualified scientific man being placed at the head. Workshop instruction is provided, and includes a knowledge of the chief wood tools, and the properties of materials, while it supplements the mechanical drawing of the schoolroom, and is an aid to the study of theoretical mechanics.

III. The course of instruction is arranged to extend over two years. In the first year the scholars take ordinary standard work, together with mathematics, mechanics, drawing, chemistry, and workshop practice.

In the second year the study of mathematics will be continued, but it is intended that the scholars shall then specialise their studies in one of the following groups: (1) Chemistry and Metallurgy. (2) Mechanics and Machine Drawing. (3) Physics and Geometry.

The peculiarity of this scheme is that it is not an attempt to benefit a few picked scholars or to provide a higher-grade school for those able to pay high fees, but that it is a continuation of the science training given by means of the peripatetic method in every ordinary elementary school under the Board.

It has already been made evident that a large capacity for scientific investigation—amounting, I believe, almost to a special genius for the study of science—exists among our English people, which has never yet received its full and fair development. The country is undoubtedly awakening to the necessity of making better provision for the study of science, in order that our manufacturers may hold their own in the markets of the world. Other and higher blessings will follow in its train. Labour, in being made intelligent, will cease to be so loveless as it often is, and the lives of toiling thousands will be filled with larger interests, guided by finer tastes, and enriched with nobler joys.

THE ASSOCIATION OF GERMAN NATURALISTS AND PHYSICIANS

THE annual gathering of this influential Society was held this year at Magdeburg during the week ending September 23, simultaneously with the yearly meetings of the German Botanical and Meteorological Associations. The proceedings were opened by the President, Dr. Gaehde, whose address was followed with a few appropriate remarks by Prof. Hochheim on the services rendered to science by Guericke and other distinguished physicists.

The formal work of the meeting was opened with a paper by Prof. Rosenbach of Göttingen, on the microscopic organisms present in festering wounds. After a brief reference to the discoveries of Koch and Ogston, the author dwelt upon his own investigations, by which he claims to have proved that all purulent matter is primarily due to minute animal organisms. The

most widespread of these germs is a yellow micrococcus, which, owing to its bunchy disposition when seen under the microscope, he has called the "grape coccus." It displays great vitality, and even after twenty or thirty years may give rise to rheumatic affections of the bones and joints. Another common species is the "chain coccus," consisting of small granular bodies strung together and presenting the appearance of chains or wreaths (Pasteur's "*chapelets*").

Owing to the colonial policy at present agitating German political and commercial circles, great interest was taken in a paper by the African explorer, Gerhard Rohlfs, on the position of Africa with regard to Germany. It contained an historic sketch of the relations of Germany with the Dark Continent, recommended the establishment of factories or trading stations in favourable places, but uttered a warning note against any premature scheme of emigration to Africa.

The second general session opened with a memoir by Prof. Braun on the Island of Yesso and its inhabitants, dealing with its geographical features, the character and social usages of its Aino aborigines, and concluding with an expression of confident assurance that sooner or later Yesso must be drawn within the sphere of European culture. Some remarks followed by Dr. Huyssen of Halle on the deep borings in the North German lowlands. A sketch was given of the borings executed since 1868 at the expense of the Prussian Government, with special reference to the results obtained in the gypsum formations at Sperenberg, twenty miles south of Berlin. Here a bed of rock-salt was met at a depth of 283 feet, through which the boring was continued down to 4051⅝ feet without reaching the bottom of the deposit. An account was given of the new method of boring, by which it became possible to sink a shaft to a depth corresponding to the height of the Brocken in the Hartz Mountains. The thermometric observations made in connection with these operations were stated to have fully confirmed previous views regarding the increased rate of temperature from the surface downwards.

Universal attention was attracted by the essay of Dr. Kirchhoff of Halle on "Darwinism and Racial Evolution," in which it was argued that the physical development of peoples was intimately dependent on the natural conditions of their respective surroundings. The inhabitants of northern lands are noted for a preponderance of the pulmonary functions; those of hot, moist, tropical regions for a more marked activity of the liver. Thus the strongest lungs prevail amongst the Mexicans, Peruvians, and Tibetans, who occupy the three highest plateaus on the surface of the globe. That adaptation to the environment is a question, not of "predestined harmony," but of natural selection, is shown by the evolution of the negro, the most perfect type of tropical man, who is found only in the Dark Continent. The daily pursuits of a people are, on the other hand, constantly evoking special organic peculiarities. This is shown most clearly in the keen sense of smell, sight, and hearing observed in all hunting and pastoral tribes of the highlands and steppe-lands, as well as in the sense of locality, and the surprising physical endurance under hunger, thirst, and other privations. Sexual selection, again, operates in the development of the body—head, hair, beard, and the like; in the style of dress and love of ornament; and lastly, in the formation of the national character, valour and ferocity being mainly conditioned in the savage, the economic and domestic virtues in civilised man, by the choice of partners in life, and the rejection of unqualified wooers in the "matrimonial market." But, apart from this consideration, the principle of selection prevails in the moral as well as in the physical order. As mankind pressed northwards, irrepressible spirits alone could sustain life under the depressing influences of bleak, Arctic surroundings. Hence the remarkably cheerful temperament of the Eskimo, who are also bred to peaceful habits, for peacefully-disposed families alone could dwell under a common roof, as the Eskimo are fain to do in the total absence of fuel. Through over-population the Chinese have become the most frugal and industrious of peoples, in recent times emigrating to foreign lands and crowding out all more indolent or pretentious races. In the international struggle for existence physical and moral superiority must always tell in the long run.

Even greater interest was taken in Prof. Finkler's paper, read with demonstrations on the bacillus of cholera and its culture. An outbreak of this epidemic last July at Bonn gave Prof. Finkler and Dr. Prior an opportunity of applying Koch's method to the study of the comma-shaped bacillus, which showed a remarkable resemblance to that of Asiatic cholera cultivated by Koch. It was found associated with large masses of the spiral-shaped organism, but with no other germ of specific appearance. These forms could not be detected in preparations of normal or any other pathological excreta under the same method of treatment. But after several failures a comma bacillus was obtained, which in its nourishment, period of evolution, and temperature behaved exactly like corresponding cultures obtained by Koch from true cholera. Still differences occurred in respect of the successive stages of evolution, which inferentially affects the question of the permanent form of the germs. After some time they become thicker, and assume somewhat the form of a whetstone, while at both extremities spore-like forms make their appearance, and take the shape of spore-bearers. Both spores are presently extruded from the spore-bearers, and begin to crawl about under the microscope. They assume the form first of straight, then of crooked rods, which develop into spirals of diverse shape, length, and curvature. Becoming thicker and swollen, these spirals in their final evolution seem to consist exclusively of small comma bacilli. But whereas the comma of Asiatic cholera, at least according to Koch's investigations, develops no permanent form, these acquire a stability in the spore state capable of resisting the process of putrefaction. Their behaviour, however, when being desiccated or subjected to chemical agents has not yet been tested by Prof. Finkler. Between the prepared specimens of cholera nostras and true cholera bacilli exhibited under the microscope no optical difference could be detected. Owing to the attitude of most German physicians, who regard it as a patriotic duty to hold Koch's doctrine as unassailable, while the German scientific journals persistently ignore the objections urged by eminent foreign investigators against the theory, Prof. Finkler's statements naturally excited considerable sensation, giving rise to an animated discussion, without however arriving at any positive results. In any case a severe blow was given to the assumption of Koch's infallibility, although Prof. Finkler and Dr. Prior have so far failed to determine the true pathogenetic and pathognostic functions of their cholera nostras comma bacillus, as completely as Koch has for his Asiatic cholera comma bacillus.

In the Section devoted to Mathematics, Astronomy, and Geodesy, Dr. Spörer of Potsdam discoursed on the determination of the elements of rotation in the sun, and on the origin of the solar spots. The theory was advocated of currents setting steadily towards the surface of the sun both from within and without.

Discussing the subject of comets' tails, Dr. A. Marcuse of Berlin assumed that the sun acted like an electro-magnet, and that the normal tails of comets consisted of diamagnetic material (carburets of hydrogen), whereas the abnormal tails, that is, those directed towards the sun, consisted of paramagnetic materials, such as iron.

In the Physical Section papers were read by Prof. Knoblauch of Halle on two fresh attempts to determine the angle of polarisation of metals; by Prof. Overbeck of Halle on galvanic polarisation; by Prof. Ostwald on galvanic resistance, dividing the acids in relation to the velocity of electrolytico-chemical reaction into three sharply separated groups according as they are uni-, bi-, or tri-basic; by Prof. Spörer on eruptions breaking through the nucleus of a solar spot; and by Prof. Recknagel on atmospheric resistance, arguing against Lössel that it increases with the size of the plates when these are circular.

The Meteorological Section, coinciding with the annual meeting of the German Meteorological Society under the presidency of Prof. Neumayer, was unusually well attended. Amongst the foreign honorary members elected on this occasion were Prof W. Ferrel of Washington, Prof. H. Mohn of Christiania, and Prof. H. Wild of St. Petersburg. In his address on the development of meteorology and its importance to the State and society, Prof. Neumayer dwelt especially on the influence of Dove, Sabine, and other investigators, as well as of the various Polar expeditions and of the British Association on the general advancement of meteorological studies. In a second discourse he referred to the importance of synoptic studies in the South Atlantic Ocean, pointing to the results already obtained from observations taken in high southern latitudes, and urging the necessity of further investigation in the same regions.

Dr. Köppen of Hamburg followed with a paper on the principles determining the distribution of meteorological stations. Discussing the question of atmospheric electricity and lightning, Dr. E. Hoppe of Hamburg argued that the ascent of a warm atmospheric current must give rise to a thunderstorm as soon as it acquires sufficient velocity to prevent the equilibrium of the

electric current generated through the condensation produced by friction. Prof. Kiessling of Hamburg made some remarks on the diffraction colours in artificially-produced fog and their connection with the recent crepuscular phenomena. In the same department papers were submitted by Dr. Münter of Herford, on the cause of winds, and by Dr. Köppen of Hamburg, on barometric disturbances during storms.

In the Chemical Section the chief speakers were: Dr. Frank of Charlottenburg, on the past technical development of the alkali works at Stassfurt, where, in July 1882, 20,000,000 cwts. of carnallite were consumed in the preparation of chloride of potassium; Prof. Poleck and Dr. T. Schiff of Breslau, on the essential oil of *Sassafras officinalis*, Neer; Prof. Poleck, on talapin; Dr. Arrhenius, on the conductive force of the electrolyte; Prof. C. Willörodt of Friburg (Baden), a contribution to the study of acetonbromoform and acetonchloroform; Prof. E. Lippmann, on a new method of representing oxygenous compounds; Dr. Leuckart of Göttingen, on a synthesis of aromatic monocarbon acids, dealing with the reciprocal action of aromatic carburets of hydrogen and cyanates in the presence of chloride of aluminium.

In the Geological and Mineralogical Section papers were read by Prof. Lossen of Berlin on the peculiar features of the geology of the Hartz Mountains; by Prof. von Fritsch of Halle on the Cretaceous floras of the Hartz; by Prof. Nehring on the diluvial fauna of the province of Sachsen and conterminous districts; by Dr. Wahnschaffe of Berlin on the Quaternary formations in the neighbourhood of Magdeburg; by Engineer Petsch of Aschersleben on the subsidence of underground waters during the process of freezing.

In the Botanical Section Prof. E. C. Hansen of Copenhagen described some new researches on certain fungi of vinous fermentation found in cow-dung and on sweet succulent fruits; A. Zimmermann, on the action of the optical elastic ellipsoid of vegetable tissues in the process of expansion: from a study of the tissues of *Nitella flexilis* and some other plants, the author concluded against Noegeli that in optical respects no fundamental contrast exists between organic and inorganic substances; W. Detmer on the formation of muriatic acid in plants; Prof. Soraner on the action of artificial freezing, describing the conduct of various vegetable tissues under the freezing process; Dr. Kaiser on the results of the determination of fossil leafy plants.

In the Section for Zoology and Comparative Anatomy, Prof. Landois of Münster spoke on the development of the shell of certain birds' eggs; Dr. H. F. Kessler of Cassel, on the evolution and life-history of the blood parasite, *Schizoneura lanigera*, Hausm.; Prof. Nehring of Berlin, on the skull and skeleton of the Peruvian dogs from the Necropolis of Ancon, with remarks on their origin: on the ground of his comparative studies, the author inferred that these dogs must have sprung from some variety of the North American wolf (*Lupus occidentalis*); Dr. Müllendorf of Berlin, on the importance of the formic acid found in honey: when closing the cells of the honeycomb, the bees mix the honey with formic acid in order to give it greater consistency; Prof. Leuckart of Leipzig, on a new species of Nematode found in the body of *Hylobius pici*, 3 mm. long, 1 mm. thick, and named *Allantiema mirabile*; Prof. W. Blasius, on some fresh data in connection with the remains of *Alca impennis*, Linn.

The excursions with which the proceedings were diversified included visits to the model Meteorological Observatory of the Magdeburg Zeitung, to the neighbouring chemical works of Stassfurt, to the University of Halle, and to the Hartz Mountains.

It was announced that the Association would hold its next annual meeting at Strasburg.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, No. 3, September 1884.—Synchronous-multiplex telegraphy in actual practice, by Prof. Edwin J. Houston (illustrated).—An extraordinary experiment in synchronous-multiplex telegraphy, by Prof. Edwin J. Houston.—On the application of electricity as an illuminating agent in astronomical observatories, by W. S. Franks.—A metastatic heat regulator, by N. A. Randolph, M.D. (one figure).—The drying of gunpowder magazines, by Prof. C. E. Munroe, U.S.N.A.—On an explanation of Hall's phenomenon, by Shelford Bidwell, M.A., LL.B. (table).—Instruction in mechanical engineering, by Prof. R. H. Thurston.—Report on the trial of the "City of Fall River," by J. E. Sague, M.E., and J. B. Adger, M.E. August 30.—Description of a universal anemometrograph (wind-gauge) recently invented by Prof. Michele Cagnassi.—Remarks on an elementary demonstration relating to the theory of the potential, by Giuseppe Vanni.—Remarks on the variations in the electric resistance of solid and pure metal wires under changes of temperature, by Prof. Angelo Emo.

Bulletin de la Société des Naturalistes de Moscou, 1883, No. 4.—On the seeming anomalies in the structure of the great comet of 1744, by Th. Bredichin (in French), with plates. It appears from calculations, illustrated by a plate, that the strips observed on this comet correspond to the "synchronal" curves of the author deduced in the hypothesis of repulsive force.—Some remarks on comets, by the same. The initial speed of their appendages towards the sun is approximately deduced at 2000 m. per second.—On the tail of the first type of the comet 1858 V., by A. Sokoloff (in French), being a calculation of "syndynamic" curves according to Bredichin's method.—On *Casona pinitorquum*, A. Br., by Ed. Kern (in German), with 4 plates.—Remarks on the geological map of the Vetluga region, by H. Trautschold.—A new Pleurotoma (*Renardii*) from the Miocene of Italy, by De Gregorio.—A new demonstration of the theorem of Lambert, by N. Joukovsky (in French); it is based on the formula of variation of action.—Materials for the geology of the Crimea, by W. Sokoloff (in Russian), being notes on the Jurassic and Neocomian deposits in the neighbourhood of Simferopol.—On the recent work of the United States geologists, by H. Trautschold.—Letter from Dr. Regel, from Tashkend.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 13.—M. Rolland, President, in the chair.—Note on the theory of the figure of the earth, by M. F. Tisserand.—On the decomposition of the oxide of copper by heat, by MM. Debray and Joannis.—Note on the sulphuret of carbon, and the application of a solution of this substance in water to the treatment of the vine attacked by phylloxera, by M. Eug. Peligot. Its solubility in water is shown to be considerably greater than that recently determined by M. Ckiandi. At the ordinary temperature water dissolves 3·5 c.c. per litre, or 4·52 grm., its density being 1·293. Its antiseptic properties have also been fully confirmed by the further investigations of M. Pasteur, who anticipates that it will become the most efficacious of all antiseptics, it being also the cheapest, costing only a few centimes per litre. It is, moreover, the best known insecticide, and has already rendered great services in the destruction of phylloxera. At present 30,000 hectares of vineyards are yearly treated with over four million kilogrammes of the sulphuret of carbon with excellent results. When applied in the form of a sulphocarbonate of potassium it has a double action, the sulphuret killing the insect, and the potassa, an essentially fertilising element, enriching the soil.—On the nitrates present in plants (continued), by MM. Berthelot and André. Their distribution during the various periods of vegetable growth, and their relation to the total proportion of the fundamental elements, potassium and nitre, contained simultaneously in the leaves, stem, root, and flower, are discussed by the authors.—Observations made at the Observatory of Marseilles during the recent total eclipse of the moon, by MM. Stéphan and Borelly. The occultations of several stars contained in the list supplied for the purpose by M. Struve of the Pulkowa Observatory were observed.—Note on the map of the erratic phenomena and ancient glaciers on the northern slope of the Swiss Alps and of the Mont Blanc range, by M. Alph. Favre. This map, drawn to the scale of 1 : 250,000, indicates the extreme development of the old glaciers, and, as far as possible, the glacial drift, erratic boulders, and moraines deposited in this region during the period of glaciation. The glacier basins, marked in different colours, by no means coincide with the present hydrographic systems of the country. Six great glaciers are enumerated: that of the Arve, stretching from Mont Blanc to Lake Bourget; that of the Rhone, running from Furca in one direction to Lyons, in another to the Rhine near Laufenburg; that of the Aar, extending from the glaciers of that name to Berne; that of the Reuss, issuing from Mont Saint-Gothard and terminating near the Rhine; that of the Limmat, stretching from the Glaris highlands to the Rhine; lastly, the vast glacier of the Rhine issuing from the Grisons, traversing Suabia, and terminating near Sigmaringen on the left bank of the Danube.—Observations made at the Observatory of Marseilles of the planets 240 and 241, and of Max Wolf's new comet, by M. Stéphan.—Description of a new galvanometer with astatic needles (one illustration), by M. E. Ducretet.—Note on the mechanical dislocation of the persistent images left on the retina of the eye after gazing on highly illuminated bodies (one illustration), by M. F. P. Le Roux.—Note on a preparation of trichlorurretted camphor, by M. Cazeneuve.—Description of the first larva from the egg of *Epicauta verticalis*, by M. H. Beauregard.—Note on two new species of simple Ascidians (family of the Phallusiadeæ), by M. Roule.—On the anatomical structure of *Anchynia rubra*, by M. N. Wagner.—Account of a new insect of the genus Phylloxera (*Phylloxera salicis*, Lichtenstein), by M. J. Lichtenstein.—Note on a meteor recently observed near Royan, by M. Chapel.—Remarks on M. Paul Venukoff's new work "On the Deposits of Devonian Formation in Russia," by M. Daubrée.—Note on a block of pumice found on April 13, fifteen miles off the Madagascar coast, in 14° 35′ S. lat., 48° 2′ E. long., and supposed to have come from the Krakatoa eruption, by M. Alph. Milne-Edwards.

STOCKHOLM

Society of Natural Sciences, September 20.—Prof. Sandahls, President, in the chair.—Dr. Wille gave an account of his researches this summer at the zoologico-botanic station established at Dr. Regnell's expense at Kristineberg, in the province of Bohus, as to the mechanical power of the higher Algæ to endure strain, and thereby resist the swell of the sea. He described his method, and gave an account of the strain which strips of Algæ of certain lengths and thicknesses could bear. He found that they possessed a very high degree of resistance and elasticity, but that when the weight was removed they retained some of the additional length caused by the strain. As might be expected, the power of resistance was greater in the lower than the upper parts, as the former suffer a far greater strain than the latter from the swell of the sea. He further referred to the anatomical causes of this, which were due to the circumstance that the specific mechanical cells which had to resist the strain were preferably developed in the lower parts, and to the fact that, as the plant grew, special organs of strengthening—they might be called moorings—were successively dropped to the bottom from the sides of the Algæ, and in some cases even developed through the membrane downwards. The lecture was illustrated by means of drawings.—Dr. Thedenius exhibited a specimen of the moss *Riccia natans*, taken by him the the same day at Sundbyberg, the only spot in Scandinavia where it grows. He also exhibited a hitherto unknown hybrid of *Tragopogon porrifolius* and *T. minor*, which had grown in his garden this summer, where both grew, and referred to the hybrid of *T. porrifolius* and *T. pratensis* found some time ago at Karlskrona. He also exhibited *Bryonia dioica*, a species never before grown in Sweden, which he had found in his garden.—The Secretary referred to an article forwarded to the Society on the East Indian plant *Abrus precatorius*, according to which a particular variety of Bacillus had been discovered in the poisonous infusion of its seed, which demonstrated that infectious diseases could be transmitted by plants, and pointed out that Dr. Widmark, a Swedish botanist, had recently shown that the Bacteria were not originally in the infusion in question, but that it only served to sustain the Bacteria which had immigrated thither from the air. He concluded by mentioning the well-known but inexplicable phenomenon of *Pinguicula vulgaris* having the effect of curdling milk when the vessels containing the latter had been rubbed with the butterwort, which was most probably due to microbes.

Botanical Society, September 27.—Prof. V. B. Wittrock, President, in the chair.—The meeting was the first one of the winter term.—On the diseases of cultivated plants in Sweden, by Herr J. Eriksson.—On the geographical extension of some rare Swedish Phanerogams, by the President.—On the 13th and 14th fasciculæ of the work "Algæ aquæ dulcis, exsiccatæ, quas distribuerunt Veit Wittrock et Otto Nordstedt," which had recently appeared, by the same.

CONTENTS

THURSDAY, OCTOBER 30, 1884

THE CHOLERA EPIDEMIC OF 1884

THE reappearance of cholera in an epidemic form in European countries after a comparatively long absence is a matter of considerable concern, not only on account of the severity of the existing epidemic but also in connection with the prospects which are in view with respect to the coming year. A great westward diffusion of cholera in the Eastern Hemisphere began in 1863, it was continued almost uninterruptedly to 1873, and the disease not only clung with considerable tenacity to certain towns and districts for two and three years at a time, but in some cases after it had apparently subsided for good, there came recrudescences of the disease after long intervals. From 1873 to the present year the greatest danger which Europe has incurred as regards cholera was during the Egyptian epidemic in 1883, but there is no reason to believe that the outbreak which is still prevailing in Southern Europe was in any way connected with that epidemic. On the contrary the evidence tends to show that it was imported by means of an imperfectly disinfected vessel, the *Sarthe*, on which cases of cholera had occurred.

Toulon was first infected about June 18, and from that date up to the present time, when only occasional deaths take place, nearly 880 fatal cases have been officially recorded there. The first cholera deaths in Marseilles occurred on June 27, the disease spread with great rapidity, reached its most fatal stage about the middle of July, and, including the few deaths that are now and again still registered there, the total mortality, according to official records, has fallen but little short of 1700. During the third week of July scattered cholera deaths occurred in a large number of the southern departments, in many localities the disease spread widely, and even during the earlier part of the present month, fresh deaths were still recorded from the department of the Pyrénées Orientales. In all, the French cholera mortality which has been recognised in official publications has, during the present year, not fallen far short of 3500.

Towards the third week in July cholera had made its appearance in Italy, and it spread with great rapidity during the month of August through the north-western part of the kingdom. Towards the end of the month several places in the south, including Naples, became infected. During September the diffusion in the north, as also in and around Naples, greatly increased; the mortality in certain towns, such as Naples, Spezia, Busca, and Genoa being very heavy. A general subsidence of the disease has now set in, but the published mortality already reaches nearly 10,300, over 6500 of the deaths having taken place in the city of Naples.

In Spain the epidemic was first officially recognised during the first week of September; it has been to a large extent limited to the province of Alicante, which abuts on the Mediterranean, and since the middle of October no further cholera deaths have been recorded. Some 100 fatal attacks are, however, known of. But whether it be Spain, Italy, or France that is in question, it is more than doubtful whether the statistics hitherto published by any means include the total deaths that have occurred. The French records are probably the most correct, but these will have to be revised before they can be regarded as in any way accurately representing the extent of the epidemic.

The very general subsidence of the epidemic which has now set in suggests two questions which are of great international importance. In the first place:—What experience has the epidemic afforded as to the measures which should properly be taken to stay the spread of cholera? The system of sanitary defence which has been adopted by France, Italy, and Spain has been quarantine; the energies of all three countries have been engaged in enforcing the system of land quarantine, with its sanitary cordons, its lazarettos, and its fumigations; and that system has utterly broken down at all points. In France the absolute impossibility of maintaining it and the uselessness of adhering to it only in part led, early in the course of the epidemic, to its abandonment, except in so far as the maintenance of certain processes of fumigation, in order to satisfy the public, are concerned. But with Italy the matter was different. No advantage had been taken of the lesson taught and bitterly enforced during the previous Italian epidemics, as to the intimate connection which exists between cholera and the retention about human dwellings of those conditions which befoul both air and water; filth abounded in by far the majority of her cities, towns, and villages; her only chance was to trust in that which had failed her before, and she clung to her cordons of troops and other allied measures with a tenacity that could not well be exceeded. But, as was pointed out by Mr. Simon many years ago, quarantine is impracticable except when planned with the precision of a scientific experiment and conducted with extreme rigour, and even then it is not conceivable as a system of national defence for the purposes of countries communicating with each other by means of great highways of traffic and of commerce. And so it has turned out. Cholera took no heed of the lines of troops, whether at the frontier or around the infected districts; it diffused itself along the lines of human intercourse as if without let or hindrance, and the very cordons and lazarettos assisted in the process of the spread; for the fear of the cordons led to the flight of an infected population before the line of bayonets could be established, and the lazarettos became, by the mere aggregation of sick and healthy under conditions as unwholesome as can well be conceived, fresh centres of infection. If it were not that the prejudices of an ignorant public had to be taken into account, land quarantine in Western Europe would probably never be heard of again. So far as measures of sea quarantine are concerned, it suffices to say that, according to the *Revue d'Hygiène*, Algeria became infected early in October by means of its communications with the southern ports of France, and that the diffusion of the disease to Spain must be regarded as having taken place by means of the sea-port of Alicante. In short, everything that has occurred during the present epidemic, including such occasional importations of choleraic cases into our ports as occurred last month at Cardiff, has gone to show that the substitution by this country of a system of medical inspection and of isolation in the place of quarantine has, both in its direct application and by the

removal of an untrustworthy system of defence, materially added to our national safety against the importation of infection.

The second question which suggests itself is:—What are the cholera prospects for Europe and this country during 1885? This question is one which it is by no means easy to answer, for to a great extent it must necessarily depend on the action that may have been and still will be taken for the removal of the conditions which are favourable to the diffusion of cholera. From the middle of 1865 to the beginning of 1869 there was probably no time when Europe could be regarded as free from the disease, and it was doubtless only a recrudescence of the same disease that led to the five years' outbreak which, commencing during the summer of 1869, was destined to prevail in one or other part of Europe up to 1874. Or to take individual countries and towns. According to the report of the late Mr. Netten Radcliffe, all the Italian provinces which suffered from cholera in 1865, with three exceptions, were again affected in 1866; the epidemic culminated in 1867, and only came to an end in January 1868. Again, the disease was more extensively diffused through France in 1866 than even in 1865; in 1867 it continued in departments previously infected, and it reappeared in some where it had ceased. In the province of Naples, cholera, commencing in 1865, did not cease until 1867. But fortunately such maintained and recurring prevalences are not the invariable rule, and even the last Neapolitan epidemic of 1873 was of much shorter duration than the earlier ones had been. The common theory that a cholera outbreak in one year is almost certain to be followed by a second one the next year is not a law of epidemics; the fact is rather due either to the failure to remove infected matter left over from the first epidemic, or, as in the case of England in 1865-66, to fresh importation of infection. In brief, it is the sanitary state of Naples, Spezia, parts of Toulon and Marseilles, and such like places, that mainly affords grounds for the fear that no intervention of winter weather can, apart from the adoption of sanitary measures on a wide scale, free the infected places from a contagium which, if left behind, may renew its activity next season. On the other hand, the maintenance of conditions of wholesome cleanliness should give a guarantee that even a fresh importation may fail to spread. Numerous importations took place into this country in 1873, and all proved abortive. Our sanitary authorities can insure a like success in 1885, even if the disease be either maintained or reappear next year in Southern Europe.

DYNAMO-ELECTRIC MACHINERY

Dynamo-Electric Machinery. By Prof. Silvanus P. Thompson. (London: E. and F. N. Spon, 1884.)

PROF. SILVANUS P. THOMPSON has undertaken the task of filling up a most important want in our scientific and technical literature; and he is to be congratulated and warmly thanked for the manner in which the task has been performed. Of the want of a scientific and practical work on dynamo-electric machinery there can be no question. The subject is at present exciting more general attention than was, perhaps, ever before given to any invention, not even excluding the steam-engine or the electric telegraph. The electric light effects are fascinating to a degree; and in these days of exhibitions and displays the natural interest in one of the most beautiful inventions has been fostered even beyond that which is natural: while speculation and even the promises of "electric light in our homes" have led to excitement which has been equally disastrous to the hopes of the many and to the progress of electric lighting itself. We are now entering it is to be hoped, or indeed have already entered, upon a more satisfactory state of things, in which hard and steady work and careful scientific investigation of every point on which efficiency and advantage in electric lighting depends will quietly bring forth an appropriate reward; and will gradually sweep away the painful impressions left by the failures of would-be electricians and of bubble companies.

Information on the subject of dynamo-electric machinery up to the present time has been very much diffused and not convenient for access, and there was great need of a careful hand to bring together as much of it as was really valuable. It consisted chiefly of a multitude of articles in the two English and two or three foreign electrical journals, and a few papers to the learned societies, generally on some special class of machine. Of English books we have scarcely any of importance except those of Mr. James Dredge and of Mr. J. E. H. Gordon, useful in their way as very handsome picture-books, and the former affording admirable detailed and figured diagrams, and a complete list of the legion of recent electric patents. A book of moderate dimensions, and written from a scientific point of view, will be welcomed alike by practical men and by theoretical students of this subject.

In Prof. Thompson's "Dynamo-Electric Machinery" we find, in five preliminary chapters, a satisfactory description of the properties of the magnetic field and of the effect of moving a coil within it; of ideal simple dynamos of different forms, accompanied by curves showing the electromotive forces produced by the rotation of rudimentary coils, the effect of superposition of electromotive forces, and the effect of the commutator. The series dynamo, shunt dynamo, and the compound-wound dynamo are likewise described in simplified form in these preliminary chapters, and likewise the various effects of electro-magnetic induction; and from these preliminary remarks there follows a long list of practical conclusions.

Chapter VI. is devoted to the government of dynamos, a subject which has engrossed a large share of the attention of practical inventors during the last four or five years. So long as electric lighting was carried on with arc lamps alone, and when the arc lamps were so imperfect as they were at that period, irregularities in the action of the dynamo machine were little noticeable in comparison with the irregularities of the arc itself. The use of the incandescent lamp, however, soon made these irregularities only too apparent; and attempts to rectify this defect in the dynamo have given rise to improvements of a very substantial character, not only as to regularity but in economy, and also in other and less important matters.

Following these preliminary chapters we find a very full and very interesting description of all the really important existing dynamos, with an account of their peculiarities and of the purposes for which each is specially

adapted. Prof. Thompson has chosen to classify dynamos according to the nature of the field of force and the manner in which the armature moves in the field of force. It is doubtless difficult to find any very satisfactory mode of classification of these machines: but the reason for the particular classification adopted here is certainly not apparent in the descriptive chapters, in which the nature and effect of the field in the various machines is perhaps the point on which a great deal mo nformation would be desirable. The diagrams and figures in these chapters are all that could be wished for. They are admirably chosen and are well executed.

The mathematical theory of the dynamo machine has of late received considerable accessions; though much yet remains to be done in working out a satisfactory theory by mathematics and experiment combined. The fundamental principles are well known. The experiments of Faraday and Joule, and the mathematical investigations of Helmholtz, Sir William Thomson, and Clerk-Maxwell have formed a good foundation; and considerable advances have recently been made by the labours of Joubert, Mascart, Hopkinson, and Marcel Deprez. The invention by Hopkinson of the "characteristic curve" is a most important step; and the study of these curves is at the present time doing for the dynamo machine the same thing that the study of Watt's indicator diagram does for the steam-engine.

Prof. Thompson devotes a considerable number of chapters to the mathematical theory of the dynamo, and his treatment of the subject is on the whole satisfactory. There are, however, a few points on which in our opinion it requires revision. One of these is the notation; and it would be a great satisfaction if mathematicians and electricians could by some means—for instance, by appointing a committee for the purpose—agree upon some standard notation which would be convenient, and which would harmonise with notations commonly employed in dynamics and in general physics. In several points we could wish to see Prof. Thompson's notation different. It seems, to say the least, a very great pity to use the letter H in mathematical writing connected with magnetism for any purpose besides Earth's Horizontal Force, while the use of the letter i for strength of the current is only a perpetuation of French want of logic.

Prof. Thompson's formulas on the subject of efficiency of a motor are not satisfactory; and it is most unfortunate that he has allowed himself to be misled by his friend, Mr. W. M. Moorsom, into fancying an error in the fundamental equation of Joubert for an alternate-current dynamo. The investigation of Appendix IV. and the physical assumption that the coefficient of self-induction for the armature and the coefficient of mutual induction for the armature and electro-magnets are approximately equal in *all* dynamos will not bear examination. It is more than doubtful whether there is *any* dynamo in which this is approximately true. Certainly it would not be true for the Siemens alternate-current machine, with which M. Joubert concerned himself. M. Joubert did not leave the matter as a question of supposition; but showed *by experiment* that the term which is concerned with mutual induction is unimportant, and that on this account the differential equation in question becomes manageable.

One other blemish we cannot pass over. It is the introduction of two or three new words which have been adopted without due weighing of the consequences. That mathematicians have been too slow to form words for new ideas we quite admit; and of the advantage of good words to express clear ideas there can be no question. Witness the comfort of having such words as "radian" for the unit angle, of "volt," "ampere," "watt." But word-making may be carried too far unless caution and judgment be used; and that words so grotesque as "torque" and as "gausses" should be adopted into the English language would be, to say the least, a very great misfortune.

The faults which we have found are, however, few, and not of vital importance, and in conclusion we must once more express our gratitude to Prof. Thompson for a very valuable work. We feel confident that it will find a very wide circle of usefulness and of appreciation.

OUR BOOK SHELF

An Elementary Treatise on Conic Sections and Algebraic Geometry, with Numerous Examples and Hints for their Solution, especially designed for the Use of Beginners. By G. Hale Puckle, M.A. (London: Macmillan & Co., 1884.)

We are not often called upon to notice the *fifth* edition of a school text-book, but now that we have examined this one and compared it with our familiar third edition copy (issued in 1868) we are glad to be able to say that, though new editions have not appeared with the sensational rapidity of some similar works of late, yet with the steady advance in public favour there has been an evident desire on Mr. Puckle's part to bring up his work to the level of other treatises on the subject. Contrasting the two editions, we find there has been an increase from 343 to 379 pages, and not only has there been careful revision, but also an addition of very many articles of interest. It is to be borne in mind that no attempt is made to bring out a work which shall satisfy the requirements of a University man who is "reading high," but the writer's aim has throughout been to write a purely *elementary* treatise on the lines of Dr. Salmon's "Conics." Mr. Puckle rightly acknowledges his great indebtedness to this now classic work, and on the other hand it should be borne in mind that the first edition came out at a time when Salmon was not openly used as a *College* text-book at Cambridge. We are very glad to notice that Mr. Puckle has, in this last edition, adopted the notation of the general equation of the second order, according to Salmon. It is quite time that this notation should be adopted in all our text-books, for it is a needless burden upon the memory to get up the several conic formulæ under different forms. A useful addition has been made to the number of worked-out exercises. A result of the book's having reached a fifth edition is that we have not noted any errata in the text.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Cretaceous Flora of North America

In the abstract of a paper on the above subject by Mr. J. Starkie Gardner in Nature of September 25 (p. 528), it is stated that "the lowest beds (of the American Cretaceous) are

distinguished by the presence of well-developed dicotyledonous leaves"; and further on these are said to occur at "the very base" of the formation. Now though such statements are sometimes loosely made, it should be understood that American geologists generally acknowledge that the base of their Cretaceous is, in some localities at least, only equivalent to the base of the Upper Cretaceous of Europe. In Canada, at least, the strictly Mesozoic flora of the Lower Cretaceous has been clearly distinguished from the angiospermous flora of the middle and upper parts of the series.

The oldest Cretaceous beds known in Canada are, I believe, those of the Queen Charlotte Islands, referred by Mr. Whiteaves, on the evidence of animal fossils, to the Neocomian age. The flora of these, consisting of cycads and conifers only, without any trace of dicotyledonous leaves, was described by me in the Report of the Geological Survey for 1873, and I remarked at the time on its decidedly Mesozoic aspect. It will be seen by reference to my memoir on the Cretaceous floras of British Columbia and the North-West Territories, in the *Transactions* of the Royal Society of Canada for 1883, that the oldest angiospermous flora known at that time in Western America is that of the Dakota group, described by Lesquereux and supposed to be of Cenomanian age. We have not yet found any dicotyledonous leaves quite so old in Canada. Our oldest angiospermous flora occurs in beds referred by Dr. G. M. Dawson and Mr. Whiteaves to the Niobrara group, which is approximately of the age of the Chalk Marl of England, in so far as can be judged by its animal fossils. A detailed table of the beds is given in the memoir above referred to, and the facts are stated in general terms in the "Descriptive Sketch" of the geology of Canada which was distributed to the members of the British Association (p. 51).

It will thus be seen that, though our angiospermous flora may possibly have appeared somewhat earlier than that of Europe, the discrepancy is by no means so great as stated in the abstract referred to. The correct statement would be, in so far as Canada and the western parts of the United States are concerned, that the oldest angiosperms known in America are probably of Cenomanian age, and that the older Cretaceous contains only, so far as known, a flora of Mesozic character. Concerning the limits of the Cretaceous and the Eocene on the one hand, and the limits of the Cretaceous and Jurassic on the other, there are no doubt some unsettled questions; but these do not affect the facts above stated. J. WM. DAWSON

Montreal, October 9

SIR J. W. DAWSON's correction only applies to the published abstract of my paper. The editor of the *Geological Magazine* having kindly offered to publish the full text, it will be seen that its scope was limited to Cretaceous dicotyledonous floras, and the older ones, to which Sir John calls attention, were purposely excluded. The title "Cretaceo-Eocene" was intended to imply that the subject was the border-land of these two formations; but I am greatly obliged for the note and the copy of the work which accompanied it. J. S. G.

Palæolithic Implements from Cambridge

ONLY two implements of Palæolithic age have been recorded from the neighbourhood of Cambridge. One of these is a rude form picked off a heap of gravel near the Observatory, and the other was bought from some workmen, and was said by them to have come from the Barnwell gravel. There is therefore considerable interest attached to the discovery of an implement of this age on the plateau between Upper Hare Park and the Cambridge Newmarket Road. This plateau is part of one of the old river terraces which formerly abutted against the hills on the east, but is now cut off from them by the valley along which the railroad to Newmarket runs. It belongs to an earlier period than that of the Barnwell gravel.

Further to the south, near Lark's Hall, in gravels which probably belong to the same set of river terraces, remains of rhinoceros, &c., have been found, but hitherto no implements or other traces of the existence of Palæolithic man have been brought to light in that district.

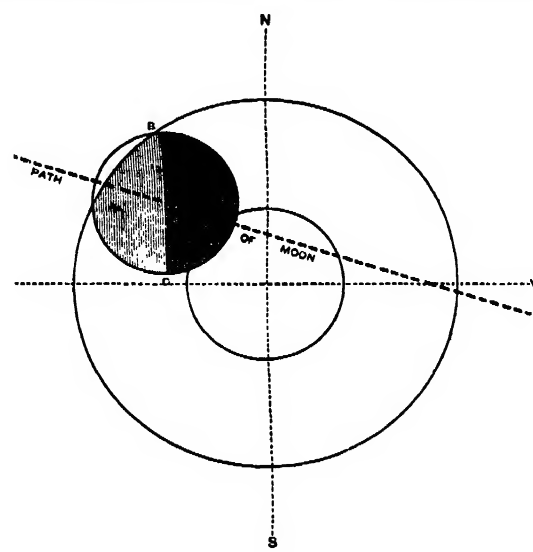
The plateau near Upper Hare Park is all unfenced arable land, and the implement which I found buried in the surface soil with only a small part of its thicker end visible, had probably been turned up out of the gravel by the plough, its surface having the same general appearance as the flints derived from the gravel. It is of the tongue-shaped St. Acheul type, and has a fine patinated surface. It measures 5½ inches in length, 3 inches across its broadest part, and nearly 1¼ at its thickest. One end is rounded so as to be easy to hold in the hand, and from this it tapers gradually with a sharp cutting edge to the point. On each side of the implement the edge is curiously rough and shattered, owing to the original quality of the flint and the way in which the flakes broke off when it was being made.

Not very far from the spot where it was found, skirting the carriage-drive which leads up to the house, are several small hollows from which vel has most likely been dug. In these hollows and all round their margin the ground is covered with flints belonging to the gravel, and amongst them I found quantities of flint chips, one or two very nicely-dressed flakes, and several scrapers.

Similar dressed flakes and scrapers are found in the caves of the South of France associated with implements of Palæolithic age; but in the case of those found near Upper Hare Park there is not sufficient evidence to prove whether they belong to the period of the gravel or were manufactured on its surface at some later period. M. C. HUGHES

The Recent Lunar Eclipse

I WONDER whether any of the readers of NATURE who were witnesses to the almost total annihilation of the moon on Saturday night, October 4, noticed a rather strange peculiarity which was visible at about 10.50 p.m., both before and after second internal contact with shadow. When the peculiarity first appeared I cannot myself say, but I noticed it first at 10.43 when I went out to look for the almost invisible moon with the aid of a good opera-glass. In the accompanying diagram, which I have constructed from the data given in the almanacs, the moon is represented as just having emerged slightly from the shadow at 10.50 or so, when the peculiarity showed very distinctly, the moon having the appearance which is roughly represented



in the diagram, being apparently divided into two halves by a tolerably distinct line of demarcation (bc) running north and south (or towards the celestial pole), the right hand or westerly half appearing much darker than the left or easterly half. It is evident that an appearance like this, so striking when once noticed, could be produced in two ways, first, by the western hemisphere of the moon being actually darker than the left or eastern half; in which case the moon would have exhibited this appearance more or less throughout totality; but it did not, as I noticed nothing of the sort at 10.15, when looking through the same glasses, so that the second explanation must be resorted to. In the diagram the larger outer circle represents the border of the earth's shadow (in the case of this eclipse about 5750 miles in diameter) which is cast by the earth, irrespective of its atmosphere. The inner circle represents the border of an inner and darker shadow of the earth, cast by those of the sun's

rays which succeed in being refracted or bent round through our atmosphere (the amount of bending of the light extending to a maximum of about 70′ in the lowest strata of the atmosphere). Into this inner circle, in this case about 2525 miles in diameter at the distance of the moon, no rays of light can stray except those which are *scattered* by our atmosphere as a sun-illumined envelope. It is now very evident that the position of the dark patch bordered by the line (*b–c*) and lying partly over the western half of the moon, with respect to the earth's shadow, is very anomalous. If the line (*bc*) had been curved concentrically to the centre of the shadow, it would have been less surprising. The only way in which it can be accounted for is by supposing the earth's atmosphere to have been very opaque about the regions of the earth within the Arctic circle, allowing very little light, if any, to be refracted, and, tracing southwards that meridian along which the moon would be setting at the time, the atmosphere getting clearer and clearer, first in the upper strata and then in the lowest as we go southwards, until the equator is nearly reached. At 10.50 the moon would be illuminated by solar rays refracted by the earth's atmosphere and tangential to the earth's surface along the meridian 105° east of Greenwich (or thereabouts), which passes through Irkutsk (in Siberia), Mongolia, Tonquin, and Siam, along which line the inhabitants would see the moon going down inveiled in its mysterious obscurity. It would be interesting to know whether any observers noticed, at about the middle of the eclipse, any contrast between the inner and darker shadow, in which the moon would be largely immersed, and the outer regions of the shadow which are illuminated dimly by both refracted and scattered light. The unusual darkness of this eclipse, surprising, as it must have done, all spectators, must be taken as a strong indication of great opacity in our atmosphere. Another noticeable feature was the unsymmetrical appearance of the illuminated crescent at 10.50, when the northern cusp (*b*) exhibited a bluish-white, shading off gradually from the brilliant white to the obscurity of the shadow, while the other cusp seemed quite sharp and distinct. Observing the eclipse both with the naked eye and through a 4½″ equatorial, neither my fellow observers nor myself noticed any other indication of a blue fringe than that appearing just at *b*, which seemed to me therefore to be a real appearance, and not a subjective effect of contrast, as there was not complementary copper colour anywhere on the moon sufficiently strong to suggest the blue, and if there had been I ought to have noticed the blue fringe all along the edge of the shadow bordering on the crescent, but it appeared to me of a neutral grey.

Heworth Green, York — H. DENNIS TAYLOR

The Red Light round the Sun—The Sun Blue or Green at Setting

I CAN confirm Mr. Backhouse's and Mr. E. D. Archibald's impression about the colour now and for some time past seen round the sun; that it first appeared about November last and has been more or less visible ever since. The colour was then, and still is, sometimes rose, sometimes amber or buff. It is best observed, when the sun on bright days is behind a cloud, round that cloud, in the place where, at other times, broken beams of shadow, thrown out from the cloud like a row of irregular palings and deepening the blue of the sky, are to be seen. Towards sunset it becomes glaring, and white and sallow in hue. Something of a circular shape may then perhaps be made out in it, but it does not seem to me that it ought to be called a halo. A halo, as I understand, is a ring, or at least a round space inclosed by a ring. This appearance has no ring round it. Also in a halo (I have seen numbers) it is the ring that is coloured—either throughout, or at four places where the ends of the four arms of a cross would rest upon it; and the inclosed field is uncoloured or coloured like the rest of the sky: here there is an uninclosed but singularly-coloured field.

But whether we call the appearance a halo or not is perhaps only a question of terms: to call it a corona, as Mr. Leslie does, is another, and, as it seems to me, a hazardous thing, because it would imply that what we are looking at is an appendage of the sun's own (and that too at a time when it is strongly doubted if the sun has a corona of any sort of all), instead of what is much easier to suppose, a terrestrial or atmospheric effect. If there is going on, as Mr. Leslie thinks, an "increase of sun power," this ought to be both felt and measured by exact instruments, not by the untrustworthy impressions of the eye. Now Prof. Piazzi-Smyth says that sunlight, as tested by the spectroscope, is weaker, not stronger, since the phenomena of last winter began. To set down variations in light and heat to changes in the sun when they may be explained by changes in our atmosphere, is like preferring the Ptolemaic to the Copernican system.

It is, however, right and important to distinguish phenomena really new from old ones first observed under new circumstances which make people unusually observant. A sun seen as green or blue for hours together is a phenomenon only witnessed after the late Krakatoa eruptions (barring some rare reports of like appearances after like outbreaks, and under other exceptional conditions); but a sun which turns green or blue just at setting is, I believe, an old and, we may say, ordinary one, little remarked till lately. I have a note of witnessing it, with other persons of a company, in North Wales on June 23, 1877, the sunset being very clear and bright. It is, possibly, an optical effect only, due to a reaction (from the red or yellow sunset light, to its complementary colour) taking place in the overstrained eye at the moment when the light is suddenly cut off, either by the sun's disappearance or by his entering a much thicker belt of vapour, which, foreshortened as the vapour is close to the horizon, may happen almost instantaneously. And this is confirmed by a kindred phenomenon of sunset. If a very clear, unclouded sun is then gazed at, it often appears not convex, but hollow; swimming—like looking down into a boiling pot or a swinging pail, or into a bowl of quicksilver shaken; and of a lustrous but indistinct blue. The sky about it appears to swell up all round into a lip or brim, and this brim is coloured pink. The colour of the light will at that time be (though the eye becomes deadened to it) between red and yellow. Now it may be noticed that when a candle-flame is looked at through coloured glass, though everything else behind the glass is strongly stained with the colour, the flame is often nearly white: I suppose the light direct from the sun's disk not only to master the red and yellow of the vapour medium, but even, to the eye, to take on something of the complementary blue.

Even since writing the above I have witnessed, though slightly, the phenomenon of a blue setting. The sunset was bright this evening, the sun of a ruddy gold, which colour it kept till nothing was left of it but a star-like spot; then this spot turned, for the twinkling of an eye, a leaden or watery blue, and vanished.

There followed a glow as bright almost as those of last year. Between 6.15 and 6.30 (Dublin time) it was intense: bronzy near the earth; above like peach, or of the blush colour on ripe hazels. It drew away southwards. It would seem as if the volcanic "wrack" had become a satellite to the earth, like Saturn's rings, and was subject to phases, of which we are now witnessing a vivid one. — G. M. H.

Dublin, October 19

The Volcanic Dust (?) Phenomena

THE changeableness of the wisps of this dust (?) is surprising. On the 19th inst., near sunset, they were conspicuously visible in all parts of the great corona round the sun, being definite in form—narrow, and about 5° long; it was the first time I had seen them since (I believe) May 18, when they were only just perceptible. During the intervening period the film or portion of the atmosphere on which the universal sky phenomena have appeared has been perfectly uniform in texture. On the 20th inst. they were again conspicuous about sunset, extending faintly even beyond the great corona; they appeared horizontal in the north-west. They were more or less visible about the same time on the 23rd and 26th, on which latter date they could be distinguished faintly in the semicircle opposite the sun at 7.30 a.m. and 4.8 p.m.

It would be interesting to know how far the changes in their visibility are simultaneous over large districts: it appears that they are not universal, for Mr. R. Leslie (NATURE, October 16, p. 583) describes them as distinct though very small in the early part of July this year, at which period I never perceived a trace of them in Switzerland. I take the "cloud forms" Mr. Leslie describes to have been the same I am alluding to, though the colour seems to have then been too faint to be perceptible at Southampton. I cannot attempt to explain how the glare round the sun was visible to him in 1882 or earlier, when the red part of what seems to be the same phenomenon did not appear till so long after.

Observations on the motion of the wisps would be very useful in showing the movements of the upper currents of the atmosphere. I have made a few, but they are not very satisfactory.

The suggestion of Prof. E. Douglas Archibald (October 9, p. 560) that the dimensions of the great corona prove it to be caused by hexagonal prisms, as is the ordinary solar halo, is surely not tenable when its entirely different appearance and colour are considered; and it must arise from a different cause as hinted by Prof. Le Conte (vol. xxix. p. 403). The solar halo is a narrow ring brightest at a distance of about 23° from the sun; whereas this corona is brightest close to the sun, fading continuously, and at first rapidly, as the distance from the sun increases. It varies somewhat in colour, depending on the sun's altitude and other causes, but is always greenish or bluish near the sun, and at an estimated distance of 7° to 10° therefrom, rather abruptly changes to reddish or brownish. This colour is nearly the same for a great distance, though inclining to orange towards the sun, and to pink in its outer part. When seen under favourable circumstances (*e.g.* in Visp-thal) I have traced it faintly to a distance of fully 75°. The solar halo, on the other hand, is usually dull orange on the edge next the sun, and bluish towards the outside; and when its colours are very distinct, all the prismatic colours are visible, the red always being next the sun: so that the colours are in reverse order in the two phenomena, so far as they occur. Whether there is any ice concerned in the production of the corona or not, it cannot be in the form of hexagonal crystals, for there is no trace of the ordinary halo in connection with the corona; and whenever the two phenomena are visible together, the halo is always on true clouds.

Sunderland, October 27 T. W. BACKHOUSE

After-Glow

THE after-glow here on Sunday night, the 26th, at 6.45 p.m., was wonderfully grand, intensely bright golden colour extending from horizon to about 45°, and graduated into delicate rose, again graduating to pale ashy gray. Indeed at no period since first observing these after-glows (now over one year) have I seen one brighter. ROBERT D. GIBNEY

The Distribution of Scientific Works Published by the British Government

RECENTLY I have enjoyed an opportunity of visiting a number of the scientific institutions of America, but it was with a feeling of humiliation that I learnt that several of the best-known and most important of them have to pay for works like the various Survey and *Challenger* Reports which are published by the British Government. It would have been possible perhaps to have obtained some statistics on the subject, but I must confess to having been restrained by a feeling of shame from making direct inquiries; what I did hear about it merely reached me in the course of casual conversation.

There are few of your readers probably who do not know of the extraordinary liberality of the American Government with reference to their publications, and when speaking of it to Major Powell, Director of the United States Geological Surveys, I was told by him that in his department it was considered that the cause of education, the spread of knowledge, and their own immediate objects were most effectually aided by a widespread distribution of their publications.

We owe much of this liberality, no doubt, to the forethought and generosity of our own countryman Smithson, the principal function of the Institution founded by him being to arrange for the exchange and despatch of books and specimens.

There are perhaps few directions in which the cause of science would be more directly benefited just now than by the establishment of an institution in England which would undertake the management of the exchanges of the scientific Societies of the United Kingdom. I am aware that there are paid agencies for the purpose, but what is wanted is a free agency which would undertake the duty for the large Societies and relieve those that are struggling from charges which now press heavily on their resources.

The great desideratum, however, is a man like Smithson, who, possessing wealth, would be willing to give or bequeath it for the purpose of founding such an institution. Here is an opportunity for any person of capital desirous of doing good and preserving his name to all posterity by one and the same act.

To return, however, to the main object of this letter, cannot anything be done to increase the "free list" of Government publications? Surely there must be stored away vast quantities of Survey and other serial publications which, if they were handed over to the Smithsonian Institute, would, I feel certain, be gratefully accepted and judiciously distributed among the libraries of America. Insect Pests in Ceylon

AMONGST the "Notes" in your last issue, p. 615, is an extract from a Ceylon paper of a report by Dr. Trimen as to an insect "which has caused much alarm by its depredations on cacao and cinchona plantations," and that Dr. Trimen thinks "the only serious damage to cacao comes from the *Helopeltis antonii*, which appears to be a recent importation to Ceylon, although well known in Java."

Quite recently I received from my friend Mr. R. McLachlan some fragments of several specimens of a Hemipteron which he had received from Ceylon, identified as *Helopeltis antonii*, and said to be causing damage to the planters' crops, and my correspondent, having doubts as to the proper identification, had forwarded the specimens (!) for my examination.

Before stating that an error of identification had been made, it is necessary to say what *Helopeltis antonii* really is. That species described by Dr. Signoret is a member of the Capsidæ, possesses nodulose or incrassated femora, and of course, like other members of that family, may be considered as injurious to some kind of vegetation. The specimens I received (*sans* head and pronotum) had also nodulose or incrassated femora, and though somewhat similar also in colour to the *Helopeltis antonii*, clearly belonged to the family Reduviidæ, whose habits and food are of a totally dissimilar character. It is therefore possible that both species occur in Ceylon; the one is being frequently mistaken for the other, a matter of some moment to the planter, as in destroying the Reduviid he may be at the same time killing the worst enemy of the real pest. The Pentacrinoid Stage of Antedon rosaceus

I WAS somewhat surprised at finding this summer, in Lamlash Bay, on the east coast of Arran, *Antedon rosaceus* in the pentacrinoid stage readily obtainable up to the end of September, and would be glad to hear from others who have been observing *Antedon*, their experience of the duration of the stalked condition. It is well known that the adult *Antedon rosaceus* is abundant at Lamlash, and that young specimens in the pentacrinoid stage are common on *Laminaria* in the earlier part of the summer; but I have always found the "pentacrinoids" rare or absent during August, and I have certainly never before found one in September. I find that the late Sir Wyville Thomson states, in his memoir "On the Embryogeny of *Antedon rosaceus*" (*Phil. Trans.* 1865, p. 513), that the ova are mature towards the end of May or beginning of June, and that, although the time spent in the larval stages may be to a certain extent shortened or prolonged by surrounding conditions, the disengagement of *Antedon rosaceus* from its stalk "constantly occurs between the middle of August and the middle of September" (p. 517). From this one would not expect to find any specimens in the pentacrinoid stage after the middle of September. This season, however, while dredging chiefly in the southern part of the bay near King's Cross Point, I obtained young stalked Antedons nearly every day between September 15 and 25. I generally got one, two, or three specimens in a forenoon's dredging (usually four or five hauls of the dredge). On September 27, the last day I dredged, I found, on some *Fucus* brought up from six or seven fathoms at the south entrance to the bay, upwards of twenty specimens of "pentacrinoids." They were of all sizes, from 3 mm. up to 1 cm. in length of stalk. The last were evidently just ready to be set free, and in fact several of them became disengaged from their stalks while I was watching them in a glass dish during the afternoon. The smaller specimens obtained that day were, from their structure, evidently very much younger, and could not have become free for a considerable time: how long I do not know, and would be glad to learn. Probably they would still have been in the pentacrinoid condition had they lived. W. A. HERDMAN

University College, Liverpool, October 21

Curious Phenomenon

A VERY curious phenomenon has just come under my notice, which is, I think, not unworthy of being put on record. I have

been staying for ten days in London, and two long white paraffin candles have been standing on the drawing-room chimney-piece all the time. We have not been using the candles; but the wicks were ignited before we came to the rooms, as it is very common to do with new candles. I noticed two days ago that the wicks were all covered over with what I at first took to be some kind of mouldy growth, but what I now find is dust which has attached itself in fine hair-like tufts to the wicks of the candles, sticking out in all directions exactly like the tufts of iron filings on a powerful magnet.

I am well acquainted with this phenomenon in the vicinity of an electric machine which is kept working continuously. For example, we find it constantly in the neighbourhood of the electrifying machine of Sir W. Thomson's siphon-recorder, where the insulating supports collect great quantities of dust, and generally in these curious forms. From the appearance of the deposits on the wicks of the candles I have very little doubt that somehow or other electric attraction has played an important part in the collecting of the dust and the formation of the filaments. But whence the electrification has come I am unable to say, unless it be that a warm current of air, which I find is always passing upwards past the candles from a wooden mantelpiece warmed by the fire, electrifies the paraffin candles and causes the phenomenon I have described.

Simson's Line

MR. J. S. MACKAY of the Edinburgh Academy, though not able to trace "Simson's line" to Simson's works (see my notice of Dr. Casey's "Euclid," NATURE, October 23, p. 607), has furnished me with the following account, which may be of general interest:—"The theorem that the orthogonal projections of a point on the circumference of a circle upon the sides of an inscribed circle are collinear is ascribed to Robert Simson by Catalan in his 'Théorèmes et Problèmes de Géométrie Élémentaire,' and he speaks several times of 'la droite de Simson.' This book of Catalan's is, I fancy, better known in the United Kingdom than many other Continental works where the same statement is made; and I conjecture that we have adopted the name from Catalan. It may, however, be the case that we have taken the information from Poncelet's 'Propriétés Projectives,' § 468, where it is said that Servois attributes the theorem to R. Simson. The passage where Servois makes this ascription occurs in Gergonne's 'Annales de Mathématiques,' vol. iv. p. 250, and it is unsatisfactory enough: 'La méthode qui vient d'être indiqué plus haut pour déterminer le point C repose sur le théorème suivant, qui est, je crois, de Simson.' I cannot carry the ascription of the theorem to Simson farther back than to Servois, and though I am not positive that Servois has made a mistake, yet I think it highly probable. The extension of the theorem to the oblique projections is attributed by Catalan to Chasles. It is due to Poncelet, and is given in the section quoted above."

THE WRITER OF THE NOTICE

October 27

A Rainbow after Sunset

ON the evening of August 29 the almanac sunset for Ireland south is placed at 6h. 51m. Happening to look out to south-south-east I saw a well-marked, though not very brilliant, portion of a rainbow in a shower cloud just above the horizon. It was not a perfect bow, but what sailors call *a dog*. I looked at the clock and saw that it was 7.15 p.m. Knowing that the sun had set, and being curious to see what could have produced the bow, I immediately went out and examined the western sky. The sun had indeed set, but there was a bright red glow and some flocculent clouds were tinged strongly with a brilliant rosy red. It was plain that the rainbow was caused by reflected light.

. Stonyford, Co. Kilkenny JAMES GRAVES

TROPICAL AFRICAN MOUNTAIN FLORA

A VERY interesting collection of plants has been brought to Kew by that intrepid African explorer Mr. Joseph Thomson, made during his late journey into the Masai country. They have been examined by Prof. Oliver, and consist of about thirty-five species from Kilimanjaro at 9000 to 10,000 feet of elevation; a few from a crater near Lake Nairasha at 7000 to 8000 feet elevation; thirty-four from the Kapté plateau at 5000 to 6000 feet; and fifty-eight from Lykipia at 6000 to 8000 feet.

These collections exhibit the mingling of North Temperate types with others characteristic of Southern Africa, for which previous discoveries had prepared us. Of these the most interesting are, as new to Tropical Africa, an Anemone, a Delphinium (very different from the Abyssinian *D. dasycaulon*), and a Cerastium of remarkable habit. Of South African forms the most striking is the handsome arborescent Rutaceous plant, *Calodendron capense*, the "wild chestnut" of Natal, to the north of which it had not previously been found. Of northern forms is a Juniper, another genus unknown to Tropical Africa, and which was found forming groves at an elevation of 6000 to 8000 feet, and itself attaining a height of 100 feet! it is the *J. procera* of Abyssinia. A *Podocarpus* gathered along with the Juniper, and also attaining 100 feet in height, is probably the *P. elongata* of Abyssinia, which, or a near ally, also occurs in South Africa. The only other Conifer previously found in the equatorial regions of Africa is the *Podocarpus Mannii* from the peak of St. Thomas in the Gulf of Guinea.

J. D. HOOKER

AN ELECTRO-DYNAMOMETER WITH EXTREMELY LIGHT SUSPENDED COIL

IN my former communications to NATURE it has, I believe, appeared (1) that the induction currents used by Du Bois-Reymond, Duchênne, and other observers for physiological and therapeutical purposes were only arbitrarily and very insufficiently measured; (2) that the simplest and most practical instrument for their measurement is a delicate electro-dynamometer; (3) that in consequence of their extreme smallness, every available method must be employed to reduce the sluggishness of such an instrument without impairing its accuracy; (4) that an instrument of this character, shown by me before the Physical Society at Oxford in June 1882, had answered very well, indeed better than a more expensive apparatus designed by Prof. Kohlrausch for larger currents.

It was, however, objected that there is an insurmountable difficulty in keeping a good contact between the aluminium and silver-gilt wires used in it for suspended coil and suspending wire respectively.

At the British Association meeting in Montreal I was able to show an improved form of the contrivance, in which this difficulty was surmounted; and, in addition, a method of damping the oscillations, which, while improving the insulation, enabled the weight of the suspended coil, on which the force of the torsion couple depends, to be varied between limits practically infinite.

The contact difficulty is met by taking a small plate of ebonite 3 mm. by 5 mm. in size, and tapping into it two small gold screws, long enough to project through, and carry two little nuts on the opposite sides. To the two screw heads the ends of the aluminium coil, bent into rings and filed flat, are firmly screwed; under the two nuts are twisted the ends of the gilt-silver suspension wires; the nuts are then similarly screwed home. Ebonite is elastic enough to render the junction air- and fluid-proof.

The second requirement was attained by coiling the aluminium wire on a thin tube of cork, and immersing it in a vessel filled with petroleum oil. Aluminium is about two and a half times heavier than water, nearly three times the specific gravity of this oil; whereas cork floats on it. Consequently, by properly proportioning the amount of cork relatively to the wire coiled on it, any desired specific gravity from absolute flotation to that of aluminium itself can be obtained. It is even practicable to load the coil, like a Sykes's hydrometer, by dropping

glass beads on a vertical aluminium wire in the axis of rotation. Here they have scarcely any influence on the swing of the coil. The damping effect of the oil, which is contained in a small globular receptacle, like a fish-bowl, between the fixed coils, is very complete and satisfactory. I had the pleasure of presenting the first rough instrument thus made to Prof. Johnson for the physical laboratory of McGill College. W. H. STONE

LIBRARY CATALOGUES[1]

THERE is a wide difference in function between the old "literary and philosophical" libraries, such as are now dying out in various parts of the country, and the "free public" libraries which are steadily, though remarkably slowly, on the increase in England—libraries which lay before readers of all classes Mr. Herbert Spencer's denunciations of what an evil sign of the times their organisation for the diffusion of knowledge is, compared with Lord Brougham's old Society for the same purpose.

The old library was in principle a museum of books, where, after a few readers who might be trusted to handle the choice volumes cautiously and reverently had enjoyed the luxury of making themselves acquainted with their contents, each of such volumes was put up in its place to form part of the "collection" of which the librarian was proud, and from which he was as little anxious to promote abundant issues as the proprietor of Dickens's old curiosity shop was to make sales of its contents!

But the other—the modern—type of library, is a stock of the literature for which either the public itself manifests the greatest appetite, or philanthropists and public educators are most desirous to disseminate and cultivate a taste: the happiest fate wished for any book in such a store being that it should be fairly thumbed to death. The new library is worked on the principle of the city warehouse where the whole stock should be turned over several times in the year; and anything which cannot be "moved" is an incubus upon which the manager's eye falls day after day with more and more impatient determinations.

The catalogues of the respective types of library accordingly should be widely different productions. That of the former should be an accurate register of sizes, dates, and editions; the compiler fairly taking it for granted that its consulter is intimate with the subject he is inquiring upon, and that a difference, even in the edition, from the one sought, may make the book as far from what he wants as Blackstone's "Commentaries" from Cæsar's.

But the main object of the catalogue of the new library is again like that of the commercial advertisement. Its consulters are not such as know exactly what they want, and its maker is anxious to display in it his books and their contents to the best advantage; like the salesman, his greatest triumph being, not to supply a customer with the article most in demand, but to allure him to higher qualifications and raise a new taste which will lead him along tempting paths of expenditure. In drawing it up, accordingly, the librarian will hardly take a better example than that of the commercial world in its advertisements of books; to be followed soberly, however, for it would doubtless raise a distrust in catalogues if they heaped up the favourable critiques which are to be found there. Nor, again, are the frequenters of a free library able to judge from titles which pleased authors' fancies what those authors' books contain, and an important matter is to bring within their ken the contents of volumes many of whose titles are indefinite, some figurative, and not a few positively misleading or absurd.

[1] "Catalogue of the Halifax Public Library, Lending and Reference Departments." (Halifax, 1882.)

In such an institution, therefore, where the books may not be examined before taking out, or the librarian have a literary discussion with each applicant, time can hardly be better spent than in making the catalogue supply as much as possible this information.

The handsome and carefully-printed catalogue now under notice, giving 100,000 references to 25,000 volumes, has carried this out to a very creditable extent; under most collected essays and doubtful titles giving a list of the subjects and the ground gone over, and under each subject-head referring the reader to the principal works where it is treated upon, or from which information may be picked up, whereas many other catalogues have placed together only those books in whose titles the name of such subject occurs. Thus under the head of Canada, while thirteen titles are quoted containing the name, there are also placed before the reader thirty-two titles which do not contain it. Although there is no book upon a special subject like "Carpets," he is referred to "Manufacturing Industries"; and under that burning subject, "Capital and Labour," though not a book bearing the title is to be found, master or man is referred to sixteen books on political economy. A danger in attempting this is shown, however, by comparing any two such catalogues together. Not half of the books in a large library bearing upon any great subject can be thus quoted, and a very intimate knowledge is required to select those of most general superiority; and even then a shade is unfairly thrown over books of nearly equal ability. Why, for instance, should only four of Hugh Miller's books be quoted under the head of Geology, and only two of those of the Geikies?

Of course this mischief increases as the greatness and importance of the subject increases. It is easy to cite all the books devoted to an account of New Zealand, but useless to attempt to give a full list of those which bear upon Europe or Asia. This catalogue carefully divides Africa into Central, East, North, South, and West, and quotes ninety-four works upon it, while upon America seventy-four make up the selection. The literature of Edward IV. may be fully compiled in a few titles, yet the forty-five works relating to Charles I. and II. do not nearly exhaust the books directly touching upon matters of that period, and sixteen works upon the English Commonwealth is not a great number to refer readers to.

Such a collection of books as the Halifax Library must have its deficiencies. Why are there only two books on the cruise of the *Challenger*, neither of them Sir Wyville Thomson's, whose name is not to be found? And if Lardner's Cyclopædia entire is not now thought indispensable, surely Thirlwall's "Greece" and some of his later books ought not to have been passed over.

It is difficult to see the advantage of the puzzling substitution in this catalogue of *A* for 10,000. It saves nothing till 10,000 is reached, and as soon as 11,000 is reached it takes up more room than the figure which requires no explanation. We are told that the Catalogue enumerates 25,000 vols., but not what substitute is made or to be made for 20,000. Again, if a —— is used to save printing an author's name a second time, why should "Capital and Labour" be printed in full nineteen times, or "United States" 125.

The printing has been unusually well corrected, but we are inclined to ask, were the "wines of Cyprus" in the head of the compiler when he quoted Mr. "Cyprus" Redding as the author of "Modern Wines"?

The date of 1882 on the title-page, while the quarterly reviews come down to the bound vols. for 1883 with tables of their contents, is explained by the first part of the work, consisting of a catalogue of the novels and books in the juvenile department which were "most in demand," being issued at the earliest date possible, Part II. containing all the more important classes not being completed till this

year. It leads to a reflection on the inevitable incompleteness of a catalogue. There is no pause in the publication of books. In spite of the most careful filling up of the lists of missing books by the librarian, and the most liberal expenditure by the Committee, hundreds of new books must have come out, and a large proportion of them added to a library, between the time when the last title is handed to the printer, and the time when the first outsider can purchase his catalogue and examine what are the treasures kept in store for him. And in no production of industry, not even in ladies' adornments, is novelty so important a recommendation as in literature. The disheartening reduction of prices in secondhand catalogues, not of three-volume novels only, but of laborious and important works, is a proof of this. A greedily read daily press makes it inevitable. Any printed catalogue, therefore, with all the books in due order, must be deficient of the favourite, if not of the most important books which the library contains. Catalogues therefore in general should be printed like the most fugitive of literature, and be renewed as frequently as possible. A card-catalogue alone can be kept on a level with the stock of books. A frequent publication by a large library of a list of its new purchases, sold at a remunerative price to students and luxurious readers, would make a library popular among those with a strong appetite for reading, while it would not lead to the older tenants of the shelves being forsaken by the crowd.

In most public libraries an effort is made to combine the functions of the old collection of books with that of the dispensary of useful or pleasing thought, by having two departments. The books more deserving of the old feeling of preservation are wisely placed apart with real works of reference to form the Reference Department. A mischievous result of this arrangement usually is that it makes books of greatest intrinsic value and forbidding costliness least available to the impecunious student. The Halifax Catalogue avoids this by arranging all together in one alphabetical list, marking each of the reference books with an *R*, and leaving the question of lending them out practically to the discretion of the librarian or Committee. We strongly approve of this method and of liberality in working it, and recommend it to the notice of other libraries. W. ODELL

THE "IDENTISCOPE"

IT appears from the *Pall Mall Gazette* of October 21 that there is a prospect of "a campaign being run in the country" on behalf of the "Claimant" by "six of the best orators whom money can collect, . . . supplied with a hundred identiscopes." These are optical instruments, containing on the one side a drawing made from a portrait of the undoubted Roger Tichborne, and on the other side a drawing made from an equally undoubted portrait of the Claimant taken nineteen years later, and the arrangement is such that on looking into the instrument the drawings combine into one. This, it is maintained, leaves no doubt that the two portraits are those of one and the same individual.

The more important of the questions raised by this announcement is whether the fact of two genuine portraits blending harmoniously into a single resultant is stringent evidence that the portraits refer to the same person. Those who have examined the optical combinations and photographic composites that I have exhibited at various times will know that this is not the case. Those who have not seen them and care to know more about the subject should look at my "Inquiries into Human Faculty." (Let me take this opportunity of correcting an error there. The full and profile composite labelled "two sisters," in the middle of the upper row of the frontispiece, is really one of three sisters. I had made many composites of the family, and by mistake sent the wrong one to the printer.) The reason why photographic portraits blend so well together is that they contain no sharp lines, but only shades. The contour of the face is always blurred, for well-known reasons dependent on the breadth of the object-glass; even the contour of the iris in an ordinary photographic print looks very coarse and irregular when it is examined by a low-power microscope. On superimposing a second portrait, the new shades fall in much the same places as the former ones; wherever they overlap they intensify one another; where they do not overlap they leave a faint penumbra which has usually a soft and not unpleasing effect. Judging from abundant experience, there would be no difficulty in selecting photographs of many different persons that should harmonise with the photograph of the Claimant, and it would be amusing to try strange combinations. I could suggest one that I think would succeed excellently: it is of a certain distinguished member of Her Majesty's——but I must be discreet, though probably if I ever come into possession of suitable photographs I may make a private experiment.

It seems, however, that the identiscope is not intended to be used to combine reproductions of the actual photographs, but only drawings in bold lines that have been made from them. The photographs, it is to be presumed, do not agree in aspect, so drawings are made from them that do so, the diameter of the iris being used as the scale unit of the breadth and length of the features, in making the drawings. Although the diameter of the iris is spoken of as an invaluable unit for exact reduction, its disadvantages appear to be great: (1) Its vertical diameter was, I suppose, not used, because in the large majority of cases the upper part of the iris is covered by the eyelid. (2) The horizontal diameter is unavailable unless the eye of the sitter was directed straight at the camera; otherwise the iris is seen in perspective, and its breadth is reduced by an unknown amount. (3) One eye is perspectively larger than the other, unless the face was set truly square to the optical axis of the lens; if not, it would be necessary to measure both eyes and to take a mean; this is a requirement to which I have as yet seen no allusion. (4) The diameter of the iris is only about 1/25th part of the length between the chin and the vertex of the head, consequently any minute error in its measurement would be largely multiplied when applying it as a unit. (5) The diameter of the iris in a photographic print does not, as I have already implied, admit of accurate measurement. The identiscope appears to be the same as an instrument sold some years ago, and of which I have one now by me. The description printed on it is "E. Wolf and Sons' patent Limnoscope, for copying drawings, designs, &c." I bought it for the purpose of experiments with composites, and tried many modifications of its principle, but other plans proved so much better that I discarded it. The principle is easily realised by any one who cares to place a table by a closed window and then to go out-of-doors with an open book in his hand, which he must hold horizontally by the side of the window, at the level of the table. He will then see through the glass an image of the book (a "Pepper's ghost," in short) resting on the table. The reflected image is so faint that the direct image has to be dimmed. Yellow glass serves this purpose. The limnoscope is not suitable for combining ordinary photographs because the reflected portrait is reversed; the left side of one face is combined with the right of the other. Much better instruments exist for making optical combinations; I have described them in my book.

I conclude as follows. First, that the fact of two photographic portraits blending harmoniously is no assurance of the identity of the persons portrayed. Secondly, when drawings made from portraits are shown to blend it does not follow that the portraits from which they were drawn would blend equally well. And lastly, the photo-

graphic print of the iris of the eye does not afford a trustworthy unit of measurement.

FRANCIS GALTON

ON THE ALGIC FLORA OF THE ARCTIC SEAS

AMONG the fields of research opened to science by the Swedish Arctic expeditions of recent years the botanical one is that which has been cultivated the most assiduously and with the best results. The contributions which Swedish men of science have made to our knowledge of the flora of the Arctic regions are varied as well as important. They embrace the higher as well as the lower forms, both the species invisible to the naked eye as well as those of greater size, and the varieties hidden in the lap of the ocean as well as those which the student encounters on *terra firma*. Swedish botanists have particularly increased our knowledge of the remarkable flora of the sea. Thus instead of, as only a few years ago, our being ignorant as to whether there really was a flora at the bottom of the Arctic seas or not, we are now more familiar with the algæ flora of these regions than many another in far more southern latitudes.

Of the Swedish botanists who have particularly devoted their time and energy to the study of the flora of the Arctic seas I must mention the following gentlemen, members of the Royal Academy of Science of Stockholm: Messrs. J. G. Agardh, P. T. Cleve, F. R. Kjellman, and E. G. Kleen. The reason which specially prompts me to discuss this subject here is the recent appearance of an important work by one of these algologists, Prof. Kjellman, viz. "Norra Ishafvets Algflora," with thirty-one illustrations, which forms part of Nordenskjöld's "*Vega*-expeditionens vetenskapliga iakttagelser," a work which has from time to time received favourable mention in this journal.

Prof. Kjellman has, as the representative of botany, and particularly the branch termed algology, participated in four Arctic expeditions, during which he has visited Finmarken, Spitzbergen, Novaya Zemlya, in Europe, and long stretches of the coast of Siberia, in Asia. Two of these expeditions, the one to Spitzbergen, 1872-73, and the *Vega* Expedition, 1878-80, were attended by winterings in the Arctic regions, during which time Prof. Kjellman enjoyed an opportunity, never before accorded to an algologist, viz. that of studying the flora of the sea *at all seasons*. His algæ flora, in consequence, not only forms a complete index of the species and varieties of the algæ of the Arctic seas, their form, construction, and geographical distribution, but it gives us also an insight into the vital functions of these plants, and explains to us the conditions under which they exist. I intend in this paper to refer briefly to the present position of this science, to which Prof. Kjellman has contributed such a great share.

The Arctic Ocean covers, geographically speaking, the sea north of the Polar Circle. Within this area there is, however, a vast tract of sea where there is no ice either winter or summer. This is the sea around Northern Norway through which the Gulf Stream flows. On the other hand, there are tracts south of the Polar Circle which rival the coldest parts of the Arctic Ocean on the point of ice. To these belongs, in the first instance, the part of the Atlantic washing the south-eastern shores of Greenland, which receives from the north a cold Polar current full of icebergs.

From a hydrographical point of view, however, the Arctic Ocean is far more naturally limited if we deduct from it the part around Northern Norway and add to it the sea around Southern Greenland. From a botanical point of view, too, the Arctic Ocean is thus limited in a more natural manner. To the part of the Arctic Ocean cut off by this arrangement Prof. Kjellman proposes to assign the name "The Norwegian Polar Sea," and in the work referred to above he deals with the algæ flora of the true Arctic Ocean, according to the hydrographical and botanical theories, as well as that of the Norwegian Polar Sea. As the conditions under which the flora of the true Arctic Ocean lives lend to the same a heightened interest, I will discuss this flora at more length, and finally add some words on that of the Norwegian Polar Sea.

In a sea like the Arctic Ocean, where ice is found in large quantities all the year round, it seems, at first sight, that no flora could exist, and it is, indeed, true that great parts of the Arctic Ocean are, botanically speaking, mere deserts, but this is not caused, as I will presently show, by the low temperature of the sea, but by other causes. Strangely enough, some algæ have become accustomed to be surrounded by a medium the temperature of which never, or at all events but seldom, rises above freezing-point, and in many instances they have indeed flourished greatly therein, of which their luxuriant growth bears evident proof.

When I just said that large tracts of the Arctic Ocean are botanically deserts, I did not thereby mean that the *deepest* parts of the sea were void of flora, as this is really the case in all, even the warmest, parts of the oceans of the globe. The algæ flora is only to be found within a smaller or larger belt along the coasts of the continents and islands, and even within this belt, where the depth does not prevent the existence of algæ, they are not found everywhere. Another condition too must be present for the existence of algæ, viz. that the bottom be rock, boulders, or marine shells, in brief, formed of large objects which can serve as "moorings" for them. Thus, where the bottom is sand or clay the regular algæ flora is absent. In the eastern parts of the Arctic Ocean the latter kind of bottom is very common. Nearly along the entire coast of Siberia, and in long stretches near Novaya Zemlya and Spitzbergen, the bottom is formed of fine sand and clay. Algæ are here sought in vain, as they are, in fact, in localities with a similar bottom all over the world. Only on the north and north-western coasts of Spitzbergen, and in several places along the west coast of Greenland, the bottom consists of such hard materials as are favourable to a copious algæ flora.

This explains to a great extent the existence of the botanical deserts, referred to above, in the Arctic Ocean, but there are also other causes. Before I deal with these, however, I must explain the manner in which the bottom of the Arctic Ocean is divided according to the flora at various depths, as suggested by Prof. Kjellman.

He distinguishes between three bottom regions, viz. the *littoral*, or what may be called the upper shore-belt, the *sub-littoral*, or lower shore-belt, and the *elittoral*, or deep-sea belt. The upper shore-belt embraces that part of the bottom which lies between the neap and high tides, the lower shore-belt the part that stretches from the former down to a depth of 36 metres, and the deep-sea belt the part below the latter depth.

Of these three belts, one, the upper belt, contributes greatly, and in a striking manner, to make parts of the Arctic Ocean flora-less. Within far the largest parts of the ocean this belt is void of all vegetation, and the cause of this is easily discovered. It lies in the ice. Thus every winter a girdle of coarse, firm ice is formed along the coast, and near the shore reaches to the bottom. In some places this ice lies all the year round, and in others it certainly disappears, but generally late in the season. At Cape Chelyuskin during the *Vega* Expedition the "ice-foot," viz. the shore-ice, was lying firm at the end of August. Where the land-ice thus remains throughout the summer no algæ can, of course, develop, and where it disappears only in the autumn the time is too short to allow of any growth.

Nearly as detrimental to the flora as the land-ice are the broken-up ice-masses, which during the summer are driven hither and thither by winds and waves. These

drift-ice masses grind the upper shore-belt to such an extent that every vestige of vegetation is decimated, if not entirely destroyed. The tide contributes also greatly to increase the disturbing influences of the ice, as by this phenomenon the area of shore exposed to the action of the ice becomes greatly increased, and by the circumstance that the ice-masses are thereby kept in *constant* motion. Not even in the winter are the ice-masses at rest along the shore. During the wintering of the Swedish expedition at Spitzbergen at the northernmost promontory of that island the sea outside the station, Mossel Bay, was covered with hard, coarse ice, some twenty miles in breadth. Still throughout the wintering a grating sound was heard from the ice, caused by the rubbing of the ice-floes and icebergs against each other as they moved backwards and forwards, or rose and fell. That a similar action would greatly affect the bottom of the sea is quite evident, particularly as most of the shores of the Arctic Ocean are void of the protection afforded by islands and fjords. The latter contribute to increase the detrimental effect of the ice on the algæ flora. On an open coast the action of the ice is, of course, more violent than where it is protected by islands. For this reason the upper shore-belt is nearly everywhere in the Arctic Ocean void of algæ where there are no protecting islands, as, for instance, on the shore of North-Western Spitzbergen, on a few places at Novaya Zemlya, and particularly at the west coast of Greenland.

Another circumstance which greatly contributes to the poorness of the algæ flora in several parts of the Arctic seas north of Asia is the brackishness of the water, caused by the great Siberian rivers. The water of the surface here consists of two parts river-water and one part sea-water, a condition which is very detrimental to the development of algæ.

The total absence of light in certain parts of the Arctic regions during a very great part of the year also arrests the growth of certain algæ which love the light. The scarcity of green algæ is, no doubt, due to this circumstance.

It is natural to assume that the temperature of the Arctic seas is low, but it is really lower than is generally believed. Thus, during the warmest part of the year, in the month of July, the mean surface temperature is from $+0^{\circ}\cdot11$ C. in the American Arctic Sea to $+3^{\circ}\cdot3$ and $4^{\circ}\cdot33$ in the sea around Spitzbergen and the Murman coast, and it decreases greatly with the depth. At the depths at which the algæ flora is richest, it never rises above 0° C. That many species of algæ are excluded from the Arctic seas by this low temperature is evident. It is, indeed, to be wondered at that there are algæ in these icy waters at all; but that there are really many I will presently show.

From what I have thus said, it appears that the algæ-covered spots in the Arctic seas are, so to speak, oases in the great Polar water desert. Let us now examine the conditions of the flora in these oases. Most of them have but a poor and sparse vegetation. This is particularly the case in the Siberian seas and the eastern part of the Kara Sea, and, to some extent, in the western part of the Kara Sea, the eastern part of the Murman Sea, the Spitzbergen Sea (the sea to the east of Spitzbergen), and the Greenland Sea (the sea between Greenland and Spitzbergen). Even where the quantity of algæ is greatest within this area, it is much less than in the richest parts of the Atlantic Ocean. In the western part of the Murman Sea and the White Sea the vegetation is not so poor (according to Chr. Gobi, "Die Algen flora des Weissen Meeres und der demselben zunächst liegenden Theile des nordlichen Eismeeres," 1878). It is richest in Baffin's Bay, on the west coast of Greenland. The greatest authority on the natural history of Greenland says on this point: "Just outside the coast of Greenland the sea-bottom is covered with a forest of giant algæ, with leaves from 12 to 16 feet in length and half a foot in width, besides which the stones are everywhere covered with coral-like layers (coral algæ)." The algæ flora in this spot is, therefore, copious, and is far in advance of those in other parts of the Arctic Ocean.

I have already said that the bottom of the Arctic Sea may be divided botanically into three belts, viz. the upper shore, the lower shore, and the deep-sea belt. Of these the first-named is the poorest, the algæ oases here being few and limited, the vegetation poor in individuals, and the algæ very small. The west coast of Greenland, with its fjords and islands, alone forms an exception in this respect. The upper belt here often produces brown algæ of considerable size (*Fucaceæ*), while even green and red are not wanting. The deep-sea belt is, like the upper one, poor in species and individuals. During the Swedish Arctic expeditions only six species have been discovered in this belt, and all of these lived at a considerable depth, one (*Ptilota pectinata*, Gunn.) even at a depth of 270 metres. The principal flora of the Arctic Sea belongs, however, to the lower shore-belt. This belt everywhere possesses the largest and the greatest number and variety of algæ. Its characteristic forms are two, viz leaf-weed algæ (*Laminarieæ*) and coral algæ (*Corallinaceæ*). They cover large areas of the bottom, and appear in close masses rich in individuals, which attain a great size. The leaf-weed algæ make the greatest impression; they derive their name from the circumstance that they carry a large leaf at the top, which is shed and renewed annually. All species belonging to this family are large algæ, some of them attaining a length of 4 metres, and the top leaf a width of 1 metre. They are the *trees* of the sea, and resemble those on land by growing together in forests. These are the algæ which in the Arctic Ocean attain the greatest size and cover the largest area, and so greatly contribute to the general habitus of the flora of this ocean that one might justly call it the "Ocean of the Laminarieæ."

Next to the Laminarieæ the Corallinaceæ are the most important. These algæ form one of the wonders of the terrestrial flora. Any one who thus sees them for the first time would think that they were real corals or some kind of stone. They are—as they appear in the Arctic seas—perfectly hard, being impregnated with chalk, and have a peculiar soft rosy or grayish-red colour. In form they vary between the laminated and the bushy. Often, too, they appear as detached ballss which have on their surface shorter or longer branch-like projections. These balls may attain a diameter of 20 centimetres, as, for instance, in *Lithothamnion glaciale* (Kjellm.), and appear in certain places in the Arctic seas in enormous quantities. On the shores of Spitzbergen and Novaya Zemlya, for instance, the bottom of the sea is for miles covered by deep layers formed of such balls, which, as Prof. Kjellman remarks, must be of great importance in forming fresh earth-crusts. All the other species of algæ play a very subordinate *rôle* compared with the Laminarieæ and Corallinaceæ. They are certainly, as regards variety of forms, superior to these latter, as the leaf-weed algæ possess only twenty species and the coral algæ nine, while other Arctic algæ—with the exception of Diatomaceæ—have as many as 145 species. In spite, however, of the abundance of the species of the latter, they make but little impression in the algæ flora, as they are either too small, or too few in the number of individuals. This being the case, it is only natural that the Arctic sea-flora, particularly owing to the predominance of the Laminarieæ, is monotonous in its appearance. This does not indeed apply to form alone, but also to colour. The colour is really sombre, the brown colour of the Laminarieæ predominating. The lighter-brown shades are almost entirely wanting. The red algæ (*Florideæ*) are not very prominent, with the exception of the coral algæ within their special sphere, and their colour is not, as I have observed, of the strongest or purest. The chlorophyll algæ are very insignificant. The many variations of green—from the freshest

grass green to the white and yellow green—which give such richness of colour to the vegetation in the Atlantic Ocean, are almost entirely absent in the Arctic seas.

I have already mentioned that leaf-weed and coral algæ attain a great size in the Arctic Ocean. This is also the case with a considerable number of other Arctic algæ. Thus, the brown algæ, *e.g. Desmarestia aculeata*, L., and *Dichloria viridis*, Müller, and the red algæ, *Delesseria sinuosa*, G. and W., and *Halosaccion ramentaceum*, L., as well as the green algæ, *Monostroma Blyttii*, Aresch., and *Chætomorpha melagonium*, W. and M., show a high degree of development; a fact which proves that these algæ not only endure, but are quite at home in, the Polar water.

Another feature of great interest relating to the subject are the biological conditions of the algæ flora. Algæ which conclude their existence in a single year are either wanting, or at all events very few. Nearly all Arctic algæ live several years, and in order that they may be able to effect the work of propagation and nourishment with the little supply there is of heat and light, their organs are in operation during the dark as well as the light season. Whilst wintering at the northernmost part of Spitzbergen in 1872-73, Prof. Kjellman observed in the middle of the winter, viz. at a time when the sun was lowest and the darkness therefore most intense, that a considerable development and growth of the organs of nourishment took place, while, as regards the organs of propagation, he found that it was just at this season that they were most developed. Spores of all kinds were produced and became mature, and they developed into splendid plants. The Arctic algæ therefore present the remarkable spectacle of plants which develop their organs of nourishment, and particularly their organs of propagation, all the year round, even during the long Polar night, growing regularly at a temperature of between $-1°$ and $-2°$ C., and even attaining a great size at a temperature which never rises above freezing-point.

The result at which Prof. Kjellman arrived with regard to the development of the Arctic flora was this, that the algæ flora of the Arctic Ocean is, contrary to the Phanerogamic flora, not an immigrant flora, but that its origin lay in the Polar Sea itself. This theory is, he believes, proved by the facts that (1) the Arctic algæ flora is rich in endemic species, these being not fewer than 37, or 22 per cent. of the whole flora); and that (2) there are many species found both in the Northern Atlantic and the Pacific Oceans a large percentage of which reaches very far north in the Arctic Sea, and which have attained a high degree of development there, being characteristic algæ of the Arctic Ocean. That the endemic species owe their origin to the Arctic Ocean cannot be doubted; and that the species referred to under (2) have been originated there and gradually spread to the other two oceans is more than probable. If this be so, Prof. Kjellman estimates the number of species whose origin must be referred to the Arctic Ocean at 100, *i.e.* about 60 per cent of the entire algæ flora.

There remain now but a few remarks to make on the algæ flora of that part of the Arctic Ocean which has been named the Norwegian Polar Sea.

If sufficient notice be taken of the geographical position, this sea may be said to be the most favoured on the globe in the way of temperature. Although north of the Polar Circle, and reaching thence to 72° N. lat., it is never frozen, not even along the coasts. The mean temperature of the sea at the North Cape during the coldest season, viz. March, April, and May, is $+3°$ C., and during the true winter months, December to February, $+3°\cdot03$ C. If to this be added that the water is very salt, and that the bottom nearly everywhere consists of rocks or boulders, and that the coast is full of fjords and islands, every condition for the development of a rich algæ flora is present. And indeed the flora here is more copious than in the true Arctic Ocean. There are no large deserts here. The upper shore-belt is covered with algæ, while brown algæ (*Fucaceæ*) are found everywhere, sometimes less, sometimes more mixed with red and green ones. The lower belt is the home of the leaf-weed algæ, most of which belong to other species than those of the true Arctic Sea. The coral algæ, too, are well represented, and even these differ from those of the true Arctic Sea in possessing brighter colours. The number of red algæ belonging to other groups is also greater than in the true Arctic Sea. The total number of algæ species in the Norwegian Polar Sea is 194, a number which is very great when we remember its limited area. There are in the true Arctic Sea, which is so much larger, only 174 species.

With regard to the general character of the algæ flora of the Norwegian Polar Sea, it must be described as a mixed flora, made up of species belonging partly to the Arctic and partly to the Atlantic Oceans, and some endemic ones. Prof. Kjellman believes, and in this I entirely concur, that the former are the original species characteristic of the spot, and that they are remnants from the time when the Arctic Ocean was larger than it is at present, *i.e.* during the Glacial period. The Atlantic species have immigrated during more recent times with the Gulf Stream, as they have by degrees become so prominent that the algæ flora of the Norwegian Polar Sea must, on the whole, now be referred to the Atlantic Ocean.

It has already been said that the algæ flora of the west coast of Greenland occupies a transitory position between that of the North Atlantic and that of the true Arctic Ocean. According to W. G. Farlow ("Marine Algæ of New England and Adjacent Coasts," 1881) this is far more the case with the algæ flora of the northern parts of the United States, and it may be of interest to note that by the aid of the Polar current flowing there a considerable number of true Arctic algæ have succeeded in penetrating to the forty-second degree of latitude, *i.e.* the latitude of Central Italy, or perhaps, more correctly speaking, have remained on the shores of New England from the very period when the Arctic Ocean extended thither at the time of the Glacial Age.

VEIT BRECHER WITTROCK
Academy of Science, Stockholm

NOTES

WE are glad to learn that the trustees have appointed Prof. Newcomb Professor of Mathematics and Astronomy in the Johns Hopkins University, and that he has agreed to accept the position. The University begins the session with 273 students, of whom 160 are graduates, and the attendance is distributed well through all the departments. Sir William Thomson's lectures, as might be expected, were a great success.

THE following changes are proposed to be made in the Council of the London Mathematical Society for the ensuing session:—Prof. Sylvester, F.R.S., and Prof. Greenhill are nominated to fill up the places vacated by the late Prof. Rowe and Mr. W. D. Niven, F.R.S. Mr. J. W. L. Glaisher, F.R.S., has been selected for the Presidentship, while Dr. Henrici, F.R.S., Prof. Sylvester, F.R.S., and Mr. J. J. Walker, F.R.S., have been nominated Vice-Presidents. In consequence of Dr. Henrici's not having yet returned from his visit to Canada and California, it is not yet certain whether he will deliver his retiring address at the annual meeting (November 13), or defer its delivery to a later date in the session. It is proposed to present the De Morgan Memorial Medal to Prof. Cayley, F.R.S., its first recipient, at the annual meeting.

LORD M'LAREN AND MR. JOHN MURRAY, two of the directors of the Ben Nevis Observatory, ascended Ben Nevis last week

and inspected the new buildings which have been erected during the summer, and which were now declared open. The new buildings include additional bedrooms and observing rooms, a tower for exit during winter and for self-registering wind instruments, and a tourists' shelter, the whole having cost over 2000*l.* The Observatory is now very completely equipped. Provisions and stores for a year have been conveyed to the top, and the observers are now fully provided for in their long winter residence. It is just a year since the Observatory was opened, and during this time hourly observations have been taken day and night without a single break. Over 2000 persons have ascended the mountain during the summer, and 1046 telegrams have been despatched by tourists to their friends in various parts of the world.

THE list of awards, medals, &c., made by the International Juries of the Health Exhibition have been announced. The total number of gold medals awarded is 278; the Society of Arts present 11 medals. The Society's Siemens Prize for the best application of gas to heating and cooking has been awarded to Mr. Thomas Fletcher. Medals for meteorological instruments, diagrams, models, &c., have been awarded to Messrs. Casella, Negretti and Zambra, Richard Frères, and Richardson and Co. For science teaching the Japanese schools have carried off medals, as well as Allan Glen's Institute, Glasgow, the Oldham School of Science, and the École Lemonnier, Paris. The Brothers of the Christian Schools have obtained in the Educational Section two gold and two silver medals and two diplomas of honour.

WE regret to announce the death of Mr. Robert Sabine, C.E., the son-in-law of Sir Charles Wheatstone. Mr. Sabine, as our readers know, has done good work in connection with the applications of electricity.

MUCH interest is manifested, both in Canada and the United States, in the enterprise of Lieut. W. R. Gordon, who was selected by the Canadian Meteorological Service for the expedition to Hudson's Bay, to establish stations for scientific observations. The work has already begun, and at each of the seven stations selected the usual meteorological observations will be made. Heavy tides will be measured; the drift of water will be noticed: and the conditions and state of the ice. Cape Hope is the most important station, and here a temporary magnetic station has been opened. This first expedition has been provided for by votes of 70,000 dollars by the Dominion Government for the purpose of obtaining reliable information as to the navigation of the Strait to the Bay, and to decide upon the feasibility of the adoption of the route as a summer outlet for the produce of the North-West. Each station party consists of two men and an Esquimaux interpreter, besides the officer in charge, and sufficient provisions and fuel for fifteen months are supplied. Lieut. Gordon, the head of the present Expedition in the *Neptune*, has been for ten years in the British Navy and five years in that of Canada. He is accompanied by Dr. Robert Bell, geologist, Charles R. Tuttle, of Winnipeg, historiographer, and seven officers. The seven stations are to be established in the following places, six on the Strait and one on the west shore of Hudson's Bay:—The first at Cape Chadley, the second on Resolution Island, the third at Cape Hope, the fourth on the north bluff of the mainland or on one of the Upper Savage Islands, the fifth on the south-east end of Nottingham Island, the sixth on the south side of Mansfield Island, and the seventh at Fort Churchill, on the mouth of the Churchill River.

IN the course of a lengthy communication to Sir Arthur Gordon, the Governor of Ceylon, suggesting improvements in the public instruction of that colony, the Rev. S. Langdon advocates the establishment of a University in Colombo, on the ground that the Universities for which Singhalese youth are now prepared are ill adapted to the requirements of Ceylon. The English University examinations are, he says, intended for a different class of candidates. They tend to a total separation of the scholarly youth of Ceylon from their own classics in favour of those of Greece and Rome. The physical science references are to examples found commonly in the British Islands, but rarely in Ceylon. With regard to the Cambridge Local Examinations, the science master of the colonial Royal College points out that in botany the Ceylon students are placed at considerable disadvantage compared with those in England, and suggests that the Cambridge Syndicate be requested to arrange that plants of tropical well-known orders of equal structural value be substituted for those given in England, and that answers to general questions, such as those referring to useful timber-trees, useful vegetables, and other plants of economic use, be recognised, if correctly given for Ceylon, as of equal value with English answers. He then selects, as an illustration of the difficulty under which a Ceylon candidate labours, questions such as these:—Compare the daisy with the dandelion; compare the rose with the buttercup; describe a fir cone, &c.; all easy enough for an English but not so for a Ceylon boy. This objection is stated to be true not only of botany, but also of other branches of natural science. The complaint is that the higher examinations for which alone the youth of the colony can be prepared are destitute of all local references, and are therefore neither calculated to develop or test an intelligent acquaintance with the subject. Besides, as the masters can prepare for any one of four foreign Universities (London, Cambridge, Calcutta, or Madras), there is little unity in the system of higher education. Moreover the expense of residing at one of these Universities deters many students from taking a University degree at all. On the whole, the case made out by Mr. Langdon in favour of a local University is, regarded from the purely educational point of view, a very strong one. He sums up this portion of his report by stating that the advantages of such a University would be—(1) unity of higher education, (2) a higher education adapted to Ceylon rather than to English requirements, (3) the correction of many present defects, especially the neglect of practical and technical studies, (4) the granting of degrees now only attainable with much expense, (5) the encouragement of vernacular education.

COMMANDER CRAWFORD PASCO, R.N., writing from Elsterwick, Victoria, N.S.W., says:—"If at *all* coast stations (lighthouses, &c.) the tide was as regularly recorded as the barometer, &c., ascertaining, where practicable, its force as well as direction, and, monthly, one simultaneous observation made at a given time, to be called a *term* day, similar to that at magnetical observatories where the clocks were set to Göttingen mean time, and for tidal purposes may be Greenwich, Washington, or any other meridian, I feel sure valuable results would be obtained."

WITH reference to the recent experiments on directing balloons, M. W. De Fonvielle explained in a recent paper, with the aid of diagrams, an elongated balloon which could be steered to the extent of being kept with the longest axis in the direction of a given current, and could be made to ascend or descend by the use of horizontal propelling screws. He further explained an adaptation he proposed of M. Dupuy de Lome's device of placing an air pouch in the balloon to compensate for loss of gas so as to form ballast air-chambers in the elongated machine.

IT will be seen from our advertising columns that some friends and fellow-workers of the late Frank Hatton desire to perpetuate his memory in the creation of an annual prize in a branch of chemistry in which he had distinguished himself at home. We heartily commend the scheme to our readers.

IN the last number of the *Agricultural Students' Gazette*, edited by students of the Royal Agricultural College, Cirencester,

will be found, besides the usual College news, "Observations on the *Œstridæ* commonly known as Bot-Flies," or warble flies, by Miss E. A. Ormerod, one of the lecturers of the College; also an interesting account of an excursion to Sir J. B. Lawes's experimental farm at Rothamsted. This little periodical holds a good place among college magazines, by the interest and value of its articles.

FROM a report by the head of the Japanese Meteorological Department on the two typhoons of August last, which caused much loss of life and damage to property, it appears that the Japanese have not had to wait long for a practical demonstration of the wisdom of their recent step in increasing the number of telegraphic weather reports from their meteorological stations to three daily. Although the second storm travelled nearly 800 miles in the course of twenty-four hours, the parts of the coasts threatened received, under the most unfavourable circumstances, several hours' warning. Mr. Knipping takes advantage of the occasion to recommend an addition to the number of signal stations which would bring them up to 150 or 200, and also to point out that Japan's most recent possession, the Loochoo Islands, is a most important meteorological outpost, for about 90 per cent. of the typhoons which ravage these regions are noticed there a day earlier than in Japan.

IN reference to a recent note on the subject, Mr. W. Mattieu Williams writes that in his "Through Norway" (published in 1877) he stated on page 108 that "the North Cape is usually described as the northernmost extremity of Europe; but this is not quite correct. There is a low glaciated tongue of rock, called *Knivskjirrodden* or *Knivskjaelodden*, about a mile to westward of North Cape, which projects farther north than the Cape itself." "It is a misnomer," he states, "to call this a 'Cape,' especially in the presence of magnificent capes which abound thereabouts. (The perpendicular face of North Cape is 974 feet high; others are above 1000 feet.) It should not be forgotten that neither North Cape nor this little ambitious out-poke is the northernmost point of the European *continent*. This distinction belongs to Nord Kyn, the North Cape and Knivskjaelodden being on Magerö, an outlying island."

THE authorities of the University of Tokio have, we observe, instructed one of their officers to devote himself wholly to the study of seismic phenomena. The gentleman selected for this purpose, Mr. Sekiya, is the Japanese Secretary to the Seismological Society of Japan, and has already had much experience in earthquake observation, which has thus become an official study in that country.

A WRITER in a recent issue of the *North China Herald* discusses the early Chinese notions of immortality. In the most ancient times ancestral worship was maintained on the ground that the souls of the dead exist after this life. The present is a part only of human existence, and men continue to be after death what they have become before it. Hence the honours accorded to men of rank in their lifetime were continued to them after their death. In the earliest utterances of Chinese national thought on this subject we find that duality which has remained the prominent feature in Chinese thinking ever since. The present life is light; the future is darkness. What the shadow is to the substance, the soul is to the body; what vapour is to water, breath is to man. By the process of cooling steam may again become water, and the transformations of animals teach us that beings inferior to man may live after death. Ancient Chinese then believed that as there is a male and female principle in all nature, a day and a night as inseparable from each thing in the universe as from the universe itself, so it is with man. In the course of ages, and in the vicissitudes of religious ideas, men came to believe more definitely in the possibility of communications with supernatural beings. In the twelfth century before the Christian era it was a distinct belief that the thoughts of the sages were to them a revelation from above. The "Book of Odes" frequently uses the expression "God spoke to them," and one sage is represented after death "moving up and down in the presence of God in heaven." A few centuries subsequently we find for the first time great men transferred in the popular imagination to the sky, it being believed that their souls took up their abode in certain constellations. This was due to the fact that the ideas of immortality had taken a new shape, and that the philosophy of the times regarded the stars of heaven as the pure essences of the grosser things belonging to this world. The pure is heavenly and the gross earthly, and therefore that which is purest on earth ascends to the regions of the stars. At the same time hermits and other ascetics began to be credited with the power of acquiring extraordinary longevity, and the stork became the animal which the Immortals preferred to ride above all others. The idea of plants which confer immunity from death soon sprang up. The fungus known as *Polyporus lucidus* was taken to be the most efficacious of all plants in guarding man from death, and three thousand ounces of silver have been asked for a single specimen. Its red colour was among the circumstances which gave it its reputation, for at this time the five colours of Babylonian astrology had been accepted as indications of good and evil fortune. This connection of a red colour with the notion of immortality through the medium of good and bad luck led to the adoption of cinnabar as the philosopher's stone, and thus to the construction of the whole system of alchemy. The plant of immortal life is spoken of in ancient Chinese literature at least a century before the mineral. In correspondence with the tree of life in Eden there was probably a Babylonian tradition which found its way to China shortly before Chinese writers mention the plant of immortality. The Chinese, not being navigators, must have got their ideas of the ocean which surrounds the world from those who were, and when they received a cosmography they would receive it with its legends.

MR. SIDNEY OLLIFF has been appointed Assistant Curator of the Australian Museum, Sydney, New South Wales.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii* ♂) from South Africa, presented by Mr. Thomas Eley; a Grivet Monkey (*Cercopithecus griseo-viridis* ♂) from West Africa, presented by Mrs. K. E. Villiers; a Common Paradoxure (*Paradoxurus typus*) from India, presented by Mrs. L. McArthur; a Hedgehog (*Erinaceus europæa*), British, presented by Mr. C. G. Hopkins; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mrs. A. M. Packard; two —— Seedeaters (*Crithagra* ——) from South Africa, presented by Mr. W. B. Cheadle, F.Z.S.; a Mute Swan (*Cygnus olor* ♂), European, presented by Lady Siemens; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, a Common Viper (*Vipera berus*), British, presented by Mr. F. H. Jennings; a Proteus (*Proteus anguinus*), European, presented by Mr. W. J. Milles; three Common Marmosets (*Hapale jacchus*) from Brazil, six Canadian Beavers (*Castor canadensis*) from Canada, two Lesser Sulphur-crested Cockatoos (*Cacatua sulphurea*) from the Moluccas, deposited; a Talapoin Monkey (*Cercopithecus talapoin*), an Allen's Galago (*Galago alleni*), a Thick-billed Pigeon (*Treron macrorhyncha*), a River Jack Viper (*Vipera rhinoceros*) from West Africa, two Horrid Rattlesnakes (*Crotalus horridus*) from Florida, purchased; four Hardwick's Mastigures (*Uromastix hardwickii*) from India, two Bengal Monitors (*Varanus bengalensis*) from Bengal, a Nilotic Crocodile (*Crocodilus vulgaris*) from Africa, received in exchange.

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—Minima of the short-period variable S Cancri may be expected about November 8, 9h. 5m.; November 27, 8h. 21m.; and December 16, 7h. 36m. The latest observations upon record were made by Schmidt in 1883: he found the star faint on March 12 at 7·2h. and March 31 at 12·8h. mean time at Athens. The star does not appear to have been much observed of late years, and further observations are needed as a check upon the period An abstract of Prof. Schönfeld's discussion on the fluctuations of this variable will be found in vol. ix. of the *Vierteljahrsschrift der Astronomischen Gesellschaft*, p. 226; he there gives as elements

Minimum = 1867 August 31, 14h. 12·24m. Paris M.T. + (9d. 11h. 37·75m.) E.

The diminution of light appears to commence about 8½ hours before the minimum; about 13 hours after minimum the star attains its usual brightness. It is therefore a variable of the Algol type. The abstract of Prof. Schönfeld's memoir referred to above is a pretty full one: the memoir itself is not to be found in the libraries either of the Royal or Royal Astronomical Societies.

Considering the great loss which this branch of observational astronomy sustained in the death of Prof. Schmidt, it is very satisfactory to find that observations of variable stars are systematically made at several Continental observatories, including the important physical establishment at Potsdam, where Dr. Wilsing is giving much attention to the subject. In the year 1883 he made upwards of 380 series of observations on 38 stars, including 24 of R Coronæ, a star which has been too much neglected. Prof. Safarik, Director of the Observatory at Prague, made numerous determinations of the brightness of some fifty stars during the same year: he mentions two *maxima* of U Geminorum, which we take to be a clerical error for *minima*. He further states that the companion of S Orionis 10·11 m., was invisible at the beginning of 1883, and continued so until April; in August it was again visible, and slowly attained 10·9 m., so that it is variable to the extent of several magnitudes, and Prof. Safarik adds, "möglicherweise alterniren seine Erscheinungen mit jenen von S Orionis." If there is reason to suspect this, the star will obviously deserve close attention. The companion precedes 2·5s., and is south 0"·4.

The positions of S Cancri and S Orionis for 1885·0 are:—

	R.A. h. m. s.	N.P.D. ° ′
S Cancri	8 37 22	70 33·1
S Orionis	5 23 20	94 46·9

Reference was made in a former column to the approaching maximum of χ Cygni about the middle of November.

WOLF'S COMET.—A circular of the Vienna Academy contains elliptical elements of this comet by Dr. Zelbr, which confirm generally the calculations of Prof. Krueger and Mr. S. C. Chandler; the period of revolution is found to be 6·76 years, the perihelion passage November 17·6739 Greenwich M.T. At midnight on that date the comet will be in R.A. 341° 50′, N.P.D. 92° 8, distant from the earth 0·979.

THE SOLAR ECLIPSE OF MARCH 16, 1885.—The commencement of this eclipse will be visible just before sunset on the west coast of Ireland. So far as we are aware, the only astronomical observatory at which it will be observable is that of Col. Cooper at Markree, which is in charge of Mr. Marth. The first contact takes place there at 5h. 43m. 58s. Markree M.T. at 86° from north point towards west, for direct image. At Valentia the eclipse begins at 5h. 40m. 22s. local mean time, at 82° from north towards west. Particulars of the track of the annular eclipse across the United States and Canada have already appeared in this column.

GEOGRAPHICAL NOTES

AN interesting pamphlet, on the systems of writing used by the various races which inhabited or still inhabit the Philippine Islands, has just been published by Señor Pardo de Tavera under the title "Contribucion para el estudio de los Antiguos Alfabetos Filipinos." It is illustrated with plates containing the alphabets discussed, which include those of the Tagals, Visayas or Bisayas, and the Battas. This archipelago offers a comparatively virgin field to students in almost every branch of inquiry. Prof. Blumentritt of Leitmeritz has devoted much study and research to the early history of the Spanish occupation of Luzon, and to the settlements of the Chinese and Japanese there during the sixteenth and seventeenth centuries, but since the publication of Jagor's work nearly thirty years ago little that is generally known in Europe has been done to solve the various problems which the languages, races, and geography of the islands present. In Spain there exists an important literature, chiefly of the last century, on the subject, and the works of Fray Gaspar, Argensola, Bravo, and others should be a mine for the modern student. The ethnology of the Negritos of the Philippines has been discussed in Germany by Dr. Mundt-Lauf; but of the wild mountain tribes of the interior, and of those who are in a state of chronic war with the Spaniards to the south of Iloilo, hardly anything is known. There is a vague surmise that some of them (the Igorrotes of Luzon, for example) are descendants of Chinese pirates of the latter end of the sixteenth century, who having attacked the Spanish settlements were defeated, and fled to the mountains, where they took themselves wives of the natives and became the progenitors of a new race.

THE last number of the *Zeitschrift der Gesellschaft für Erdkunde zu Berlin* contains a long paper by Prof. Blumentritt on the Island of Mindanao, the second largest of the Philippine Islands, accompanied by an excellent map, based on numerous Spanish maps. The writer enters at length into the geography and ethnology of the island, dealing in successive sections with the mountains, hydrography, political divisions, population, and the eighteen tribes which inhabit it. With regard to the last section of his subject, Prof. Blumentritt says that if we omit the few Europeans, Creoles, Mestizos, and Chinese, the natives of Mindanao may be divided into Negritos and Malays. The former are subdivided into Mamanuás and Atas, while the latter are composed of a series of tribes which may be approximately placed according to their religion under three heads: (1) the Visayas, or "Old Christians"; (2) the mountain tribes, who are either Pagans or Conquistas; (3) the Moros (Moors), who are Mohammedans. The Visayas and Moors are late-comers; the former arrived within the period of Spanish rule in the island from the archipelago lying to the north, which at present bears the name of the Visaya Islands; the Moros also came recently from Borneo and Ternate. Our knowledge of the mountain tribes, says Prof. Blumentritt, is not sufficient to enable us to state definitely what relation they bear to the Visayas, or to the head-hunters of Borneo and Luzon. In the following sections of his paper the writer gives all the information available respecting these tribes, his sources being chiefly the reports of Spanish missionaries. In many cases this information is of the vaguest possible description. In addition to the eighteen tribes here mentioned, there are no fewer than fourteen States with independent Sultans amongst the Moros of Mindanao.

THE same number of the *Zeitschrift* also contains a paper (with a map) on the Loochoo Islands, by Herr Müller-Beeck. It appears to be wholly taken from reports furnished to the Japanese Government by an official who visited the archipelago several times for the purpose of investigation. The paper adds little to our knowledge of the islands, because there is probably not a great deal to know about them geographically. By the way, Herr Muller-Beeck is in error in attributing the name Lin-choten, as applied to the seven islands of the northern group called Shichi-to, to the English. This corruption is due to the Dutch, and like many similar corruptions still retains its place in our Admiralty charts as the name by which the islands are known to European navigators.

M. BRAU DE SAINT-POL LIAS, who, as recently mentioned in NATURE, has been commissioned by the French Minister of Public Instruction to make a natural history collection in Sumatra and Java, is an experienced traveller in those regions. Not long since he published a work on Perak, in the Malay Peninsula, and the tribes inhabiting it. He has now issued another small volume on the Acheenese, under the title of "Chez les Atchés-Lohong" (Paris, Plon). Having made friends with the headman of Lohong, he was able to travel freely in that portion of Sumatra, and to observe the customs of the natives. Not long before, two of his countrymen were murdered in neighbouring territory, through which, however, M. Lias was allowed to pass. He appears also to have travelled near the now notorious Tenom, where the unfortunate crew of the *Nisero* were so long confined, and on the whole to have enjoyed advantages for obtaining information about this little-known region—although

it lies within a few miles of the path of the greater part of the trade of Europe with the Far East—than any previous traveller. The apparently interminable war between the Dutch and the natives of Sumatra renders travelling or investigation in that marvellous island all but impossible to Europeans.

AT a meeting of the Society for Commercial Geography of Paris, held on the 21st inst. under the presidency of M. Meurand, Dr. Neis, of the Naval Medical Service, recounted the incidents of a recent journey from Saigon to the frontiers of Tonquin, and thence to Bangkok. He travelled from the basin of the Meikong to that of the Meinam, and referred in his paper to the various tribes met on the frontiers of Tonquin and Cambodia, and to the progress of England in Siam and Burmah. The Society, we observe, now numbers 1000 members.

THE following is a list of the papers arranged to be read before the Society for Commercial Geography of Oporto during the ensuing winter session:—Useful animals of Portugal and its possessions, by M. Torgo, jun.; crime from climatological and ethnological points of view, by M. Veloso; the geography of the Azores, by M. Silva; the exportation of national products to Brazil and the Portuguese colonies, by M. Gonsalvez; the climatological geography of the Portuguese colonies, by M. Monteira; recent colonial treaties with England, by M. de Sonza.

Petermann's Mittheilungen for October contains an article on the south-western portion of the province of Ciudad-Real, in Spain, with a map, by Herr Otto Neussel; one by Dr. Roukis, on the ethnography and statistics of Albania, based on a series of articles contributed to the Athens journal *Akropolis*, under the title of "The Present and the Future of Albania," by the late Greek Consul-General in that country; a third paper on Terek is a translation of one read before the Caucasian section of the Russian Geographical Society by Herr Dinnik. The "Recent Information from Corea" is that published in English Blue-books as reports from various consular officials who have lately visited the peninsula.

NOTES ON NITRIFICATION[1]

IN the following brief notes I propose to consider in the first place the present position of the theory of nitrification, and next to give a short account of the results of some recent experiments conducted in the Rothamsted Laboratory.

The Theory of Nitrification.—The production of nitrates in soils, and in waters contaminated with sewage, are facts thoroughly familiar to chemists. It is also well known that ammonia, and various nitrogenous organic matters, are the materials from which the nitric acid is produced. Till the commencement of 1877 it was generally supposed that this formation of nitrates from ammonia or nitrogenous organic matter was the result of simple oxidation by the atmosphere. In the case of soil it was imagined that the action of the atmosphere was intensified by the condensation of oxygen in the pores of the soil; in the case of waters no such assumption was possible. This theory was most unsatisfactory, as neither solutions of pure ammonia, or of any of its salts, could be nitrified in the laboratory by simple exposure to air. The assumed condensation of oxygen in the pores of the soil also proved to be a fiction as soon as it was put by Schlœsing to the test of experiment.

Early in 1877, two French chemists, Messrs. Schlœsing and Müntz, published preliminary experiments showing that nitrification in sewage and in soils is the result of the action of an organised ferment, which occurs abundantly in soils and in most impure waters. This entirely new view of the process of nitrification has been amply confirmed both by the later experiments of Schlœsing and Muntz, and by the investigations of other chemists, amongst which are those by myself conducted in the Rothamsted Laboratory.

The evidence for the ferment theory of nitrification is now very complete. Nitrification in soils and waters is found to be strictly limited to the range of temperature within which the vital activity of living ferments is confined. Thus nitrification proceeds with extreme slowness near the freezing-point, and increases in activity with a rise in temperature till 37° are reached; the action then diminishes, and ceases altogether at 55°. Nitrification is also dependent on the presence of plant-food suitable for organisms of low character. Recent experiments at Rothamsted show that in the absence of phosphates no nitrification will occur. Further proof of the ferment theory is afforded by the fact that antiseptics are fatal to nitrification. In the presence of a small quantity of chloroform, carbon bisulphide, salicylic acid, and apparently also phenol, nitrification entirely ceases. The action of heat is equally confirmatory. Raising sewage to the boiling-point entirely prevents its undergoing nitrification. The heating of soil to the same temperature effectually destroys its nitrifying power. Finally, nitrification can be started in boiled sewage, or in other sterilised liquid of suitable composition, by the addition of a few particles of fresh surface soil, or a few drops of a solution which has already nitrified; though without such addition these liquids may be freely exposed to filtered air without nitrification taking place.

The nitrifying organism has been submitted as yet to but little microscopical study: it is apparently a micrococcus.

It is difficult to conceive how the evidence for the ferment theory of nitrification could be further strengthened; it is apparently complete in every part. Although, however, nearly the whole of this evidence has been before the scientific public for more than seven years, the ferment theory of nitrification can hardly be said to have obtained any general acceptance; it has not indeed been seriously controverted, but neither has it been embraced. In hardly a single manual of chemistry is the production of saltpetre attributed to the action of a living ferment existing in the soil. Still more striking is the absence of any recognition of the evidence just mentioned when we turn to the literature and to the public discussions on the subjects of sewage, the pollution of river water, and other sanitary questions. The oxidation of the nitrogenous organic matter of river water is still spoken of by some as determined by mere contact with atmospheric oxygen, and the agitation of the water with air as a certain means of effecting oxidation; while by others the oxidation of nitrogenous organic matter in a river is denied, simply because free contact with air is not alone sufficient to produce oxidation. How much light would immediately be thrown on such questions if it were recognised that the oxidation of organic matter in our rivers is determined solely by the agency of *life*, is strictly limited to those conditions within which life is possible, and is most active in those circumstances in which life is most vigorous. It is surely most important that scientific men should make up their minds as to the real nature of those processes of oxidation of which nitrification is an example. If the ferment theory be doubted, let further experiments be made to test it, but let chemists no longer go on ignoring the weighty evidence which has been laid before them. It is partly with the view of calling the attention of English and American chemists to the importance of a decision on this question that I have been induced to bring this subject before them on the present occasion. I need hardly add that such results as the nitrification of sewage by passing it through sand, or the nitrification of dilute solutions of blood prepared without special precaution, are no evidence whatever against the ferment theory of nitrification. If it is to be shown that nitrification will occur in the absence of any ferment, it is clear that all ferments must be rigidly excluded during the experiments; the solutions must be sterilised by heat, the apparatus purified in a similar manner, and all subsequent access of organisms carefully guarded against. It is only experiments made in this way that can have any weight in deciding the question.

Leaving now the theory of nitrification, I will proceed to say a few words, firstly, as to the distribution of the nitrifying organism in the soil; secondly, as to the substances which are susceptible of nitrification; thirdly, upon certain conditions having great influence on the process.

The Distribution of the Nitrifying Organism in the Soil.—Three series of experiments have been made on the distribution of the nitrifying organism in the clay soil and subsoil at Rothamsted. Advantage was taken of the fact that deep pits had been dug in one of the experimental fields for the purpose of obtaining samples of the soil and subsoil. Small quantities of soil were taken from freshly-cut surfaces on the sides of these pits at depths varying from 2 inches to 8 feet. The soil removed was at once transferred to a sterilised solution of diluted urine, which was afterwards examined from time to time to ascertain if nitrification took place. These experiments are hardly yet completed; the two earlier series of solutions have, however, been examined for eight and seven months respectively. In both these series the soil taken from 2 inches, 9 inches, and

[1] A Paper by R. Warington, read before the Chemical Section of the British Association at Montreal.

18 inches from the surface has been proved to contain the nitrifying organism by the fact that it has produced nitrification in the solutions to which it was added; while in twelve distinct experiments made with soil from greater depths no nitrification has yet occurred, and we must therefore conclude that the nitrifying organism was not present in the samples of soil taken. The third series of experiments has continued as yet but three months and a half; at present no nitrification has occurred with soil taken below 9 inches from the surface. It would appear, therefore, that in a clay soil the nitrifying organism is confined to about 18 inches from the surface; it is most abundant in the first 6 inches. It is quite possible, however, that in the channels caused by worms, or by the roots of plants, the organism may occur at greater depths. In a sandy soil we should expect to find the organism at a lower level than in clay, but of this we have as yet no evidence. The facts here mentioned are in accordance with the microscopical observations made by Koch, who states that the micro-organisms in the soils he has investigated diminish rapidly in number with an increasing depth; and that at a depth of scarcely 1 metre the soil is almost entirely free from bacteria.

Some very practical conclusions may be drawn from the facts now stated. It appears that the oxidation of nitrogenous matter in soil will be confined to matter near the surface. The nitrates found in the subsoil and in subsoil drainage waters have really been produced in the upper layer of the soil, and have been carried down by diffusion, or by a descending column of water. Again, in arranging a filter-bed for the oxidation of sewage, it is obvious that, with a heavy soil lying in its natural state of consolidation, very little will be gained by making the filter-bed of considerable depth; while, if an artificial bed is to be constructed, it is clearly the top soil, rich in oxidising organisms, which should be exclusively employed.

The Substances susceptible of Nitrification.—The analyses of soils and drainage waters have taught us that the nitrogenous humic matter resulting from the decay of plants is nitrifiable; also that the various nitrogenous manures applied to land, as farmyard manure, bones, fish, blood, rape-cake, and ammonium salts, undergo nitrification in the soil. Illustrations of many of these facts from the results obtained in the experimental fields at Rothamsted, have been published by Sir J. B. Lawes, Dr. J. H. Gilbert, and myself, in a recent volume of the *Journal* of the Royal Agricultural Society of England. In the Rothamsted Laboratory, experiments have also been made on the nitrification of solutions of various substances. Besides solutions containing ammonium salts and urea, I have succeeded in nitrifying solutions of asparagine, milk, and rape-cake. Thus, besides ammonia, two amides, and two forms of albuminoids have been found susceptible of nitrification. In all cases in which amides or albuminoids were employed, the formation of ammonia preceded the production of nitric acid. Mr. C. F. A. Tuxen has already published in the present year two series of experiments on the formation of ammonia and nitric acids in soils to which bone-meal, fish-guano, or stable-manure had been applied; in all cases he found the formation of ammonia preceded the formation of nitric acid.

As ammonia is so readily nitrifiable, we may safely assert that every nitrogenous substance which yields ammonia when acted on by the organisms present in soil is also nitrifiable.

Certain Conditions having Great Influence on the Process of Nitrification.—If we suppose that a solution containing a nitrifiable substance is supplied with the nitrifying organism, and with the various food-constituents necessary for its growth and activity, the rapidity of nitrification will depend on a variety of circumstances:—(1) The degree of concentration of the solution is important. Nitrification always commences first in the weakest solution, and there is probably in the case of every solution a limit of concentration beyond which nitrification is impossible. (2) The temperature has great influence. Nitrification proceeds far more rapidly in summer than in winter. (3) The presence or absence of light is important. Nitrification is most rapid in darkness; and in the case of solutions, exposure to strong light may cause nitrification to cease altogether. (4) The presence of oxygen is of course essential. A thin layer of solution will nitrify sooner than a deep layer, owing to the larger proportion of oxygen available. The influence of depth of fluid is most conspicuous in the case of strong solutions. (5) The quantity of nitrifying organism present has also a marked effect. A solution seeded with a very small amount of organism will for a long time exhibit no nitrification, the organism being (unlike some other bacteria) of very slow growth. A solution receiving an abundant supply of the ferment will exhibit speedy nitrification, and strong solutions may by this means be successfully nitrified, which with small seedings would prove very refractory. The speedy nitrification which occurs in soil (far more speedy than in experiments in solutions under any conditions yet tried) is probably owing to the great mass of nitrifying organisms which soil contains, and to the thinness of the liquid layer which covers the soil particles. (6) The rapidity of nitrification also depends on the degree of alkalinity of the solution. Nitrification will not take place in an acid solution, it is essential that some base should be present with which the nitric acid may combine; when all available base is used up nitrification ceases. It appeared of interest to ascertain to what extent nitrification would proceed in a dilute solution of urine without the addition of any substance save the nitrifying ferment. As urea is converted into ammonium carbonate in the first stage of the action of the ferment, a supply of salifiable base would at first be present, but would gradually be consumed. The result of the experiment showed that only one-half the quantity of nitric acid was formed in the simple urine solution as in similar solutions containing calcium and sodium carbonate. The nitrification of the urine had evidently proceeded till the whole of the ammonium had been changed into ammonium nitrate, and the action had then ceased. This fact is of practical importance. Sewage will be thoroughly nitrified only when a sufficient supply of calcium carbonate, or some other base, is available. If, instead of calcium carbonate, a soluble alkaline salt is present, the quantity must be small, or nitrification will be seriously hindered. Sodium carbonate begins to have a retarding influence on the commencement of nitrification when its amount exceeds 300 milligrammes per litre, and up to the present time I have been unable to produce an effective nitrification in solutions containing 1·000 gramme per litre. Sodium hydrogen carbonate hinders far less the commencement of nitrification. Ammonium carbonate, when above a certain amount, also prevents the commencement of nitrification. The strongest solution in which nitrification has at present commenced contained ammonium carbonate equivalent to 368 milligrammes of nitrogen per litre. This hindrance of nitrification by the presence of an excess of ammonium carbonate effectually prevents the nitrification of strong solutions of urine, in which, as already mentioned, ammonium carbonate is the first product of fermentation. Far stronger solutions of ammonium chloride can be nitrified than of ammonium carbonate, if the solution of the former salt is supplied with calcium carbonate. Nitrification has in fact commenced in chloride of ammonium solutions containing more than 2 grammes of nitrogen per litre.

The details of the recent experiments, some of the results of which we have now described, will, it is hoped, shortly appear in the *Journal* of the Chemical Society of London.

Harpenden, July 21

RESEARCHES ON THE ORIGIN AND LIFE-HISTORIES OF THE LEAST AND LOWEST LIVING THINGS[1]

II.

BUT the point of difficulty was *B. termo*. The demonstration of its flagella was a task of difficulty which only patient purpose could conquer. But by the use of our new lenses, and special illumination we—my colleague and I—were enabled to demonstrate clearly a flagellum at each end of this least of living organisms, as you see, and by the rapid lashing of the fluid, alternately or together, with these flagella, the powerful, rapid, and graceful movements of this smallest known living thing are accomplished. Of course these fibres are inconceivably fine—indeed for this very reason it was desirable, if possible, to *measure* it, to discover its actual thickness. We all know that, both for the telescope and the microscope, beautiful apparatus are made for measuring minute magnified details. But unfortunately no instrument manufactured was delicate enough to measure *directly* this fibre. If it were measured it must be by an indirect process, which I accomplished thus:—The diameter of the body of *B. termo*, *i.e.* from side to side, may, in different forms vary from the 20- to the 50-thousandth of an inch. *That* is a measurement which we may easily make directly with a micrometer. Having ascertained this, I deter-

[1] By Rev. W. H. Dallinger, LL.D., F.R.S., F.L.S., Pres.R M S. Continued from p. 622.

mined to discover the ratio of thickness between the body of the Bacterium and its flagellum—that is to say, to discover how many of the flagella laid side by side would make up the width of the body.

I proceeded thus. This is a complicated microscope placed on a tripod, so arranged that it may be conveniently worked upright. There is a special instrument for centering and illuminating. On the stage of the instrument, the Bacterium with its flagellum in distinct focus is placed. Instead of the simple eyepiece a *camera lucida* is placed upon it. This instrument is so constructed that it appears to throw the image of the object upon the white sheet of paper on the small table at the right hand where the drawing is made, at the same time that it enables the same eye to see the pencil and the right hand. In this way I made a careful drawing of *B. termo* and its flagellum, magnified 5000 diameters. Here is a projection of the drawing made. But I subsequently avoided paper, and used under the camera a most carefully prepared surface of ground glass. When the drawing was made I placed on the drawing a drop of Canada balsam, and covered it with a circle of thin glass, just like any other microscopic mounted object. This is a micro-slide so prepared. Now you can see that I only have to lay this on the stage of a microscope, make it an object for a low power, and use a screw micrometer to find how many flagella go to the making of a body. The result is given in the figure: you see that *ten flagella would fill the area occupied by the diameter of the body.*

In the case chosen the body was the 1/20400th of an inch wide, and therefore, when divided by ten, gave for the flagellum a thickness of the 1/204000th of an English inch. In the end I made fifty separate drawings with four separate lenses. I averaged the result in each fifty; and then took the average of the total of 200, and the mean value of the width of the flagellum was the 1/204700th of an English inch. It will be seen, then, that we are possessed of instruments which, when competently used, will enable us to study the life-histories of the putrefactive organisms, although they are the minutest forms of life. I have stated that they were the inevitable accompaniments of putrescence and decay. You learned from a previous illustration the general appearance of the Bacteria: they are the earliest to appear whenever putrefaction shows itself. In fact, *the pioneer is this—the ubiquitous Bacterium termo.* The order of succession of the other forms is by no means certain. But whenever a high stage of decomposition is reached a group of forms represented by these three will swarm the fluid. These are the Monads, they are strictly putrefactive organisms, they are midway in size between the least and largest Bacteria, and are, from their form and other conditions, more amenable to research, and twelve years ago I resolved, with the highest power lenses and considerable practice in their use, to attack the problem of their origin; whether as physical products of the not-living, or as the natural progeny of parents.

But you will remember that only a minute drop of fluid containing them can be examined at one time. This minute drop has to be covered with a minute film of glass not more than the 200th of an inch thick. The highest lenses are employed, working so near as almost to touch the delicate cover. Clearly, then, the film of fluid would rapidly evaporate and cause the destruction of the object studied. To prevent this an arrangement was devised by which the lens and the covered fluid under examination were used in an air-tight chamber, the air of which was kept in a saturated condition; so that being like a saturated sponge unable to take in any more it left the film of fluid unaffected. But to make the work efficient I soon found that there must be a second observer. Observation by leaps was of no avail. To be accurate it must be unbroken. There must be no gap in a chain of demonstration. A thousand mishaps would occur in trying to follow a single organism through all the changes of successive hours to the end. But, however many failures, it was evident we must begin on another form at the earliest point again, and follow it to the close. I saw soon that every other method would have been merely empirical, a mere piecemeal of imagination and fact. When one observer's ability to continue a long observation was exhausted, there must be another at hand to take up the thread and continue it; and thus to the end. I was fortunate indeed at this time in securing the ready and enthusiastic aid of Dr. J. J. Drysdale, of Liverpool, who practically lived with me for the purpose and went side by side with me to the work. We admitted nothing which we had not both seen, and we succeeded each other consecutively, whenever needful, in following to the end the complete life-histories of six of these remarkable forms.

I will now give you the facts in relation to two which shall be typical. We obtained them in enormous abundance in a maceration of fish. I will not take them in the order of our researches, but shall find it best to examine the largest and the smallest. The appearance of the former is now before you. It is divergent from the common type when seen in its perfect condition, avoiding the oval form, but it resumes it in metamorphosis. It is comparatively huge in its proportions, its average extreme length being the 1,000th of an inch. Its normal form is rigidly adhered to as that of a rotifer or a crustacean. Its body-substance is a structureless sarcode. Its differentiations are a nucleus-like body, not common to the monads; generally a pair of dilating vacuoles, which open and close like the human eyelid, ten to twenty times in every minute; and lastly, the unusual number of four flagella. That the power of motion in these forms and in the Bacteria is dependent upon these flagella I believe there can be no reasonable doubt. In the monads, the versatility, rapidity, and power of movement are always correlated with the number of these. The one before us could sweep across the field with majestic slowness, or dart with lightning swiftness and a swallow's grace. It could gyrate in a spiral, or spin on its axis in a rectilinear path like a rifled bullet. It could dart up or down, and begin, arrest, or change its motion with a grace and power which at once astonish and entrance. Fixing on one of these monads then, we followed it doggedly by a never ceasing movement of a "mechanical stage," never for an instant losing it through all its wanderings and gyrations. We found that in the course of minutes, or of hours, the sharpness of its outline slowly vanish, its vacuoles disappear, and it lost its sharp caudal extremity, and was sluggishly amœboid. This condition intensified, the amœboid action quickened as here depicted, the agility of motion ceased, the nucleus body became strongly developed, and the whole sarcode was in a state of vivid and glittering action.

If now it be sharply and specially looked for it will be seen that the root of the flagella *splits*, dividing henceforth into two separate pairs. At the same moment a motion is set up which pulls the divided pairs asunder, making the interval of sarcode to grow constantly greater between them. During this time the nuclear body has commenced and continued a process of self-division; from this moment the organism grows rapidly rounder, the flagella swiftly diverge. A bean-like form is taken; the nucleus divides, and a constriction is suddenly developed; this deepens; the opposite position of the flagella ensues, the nearly divided forms now vigorously pull in opposite directions, the constriction is thus deepened and the tail formed. The fibre of sarcode, to which the constricted part has by tension been reduced, now snaps, and two organisms go free. It will have struck you that the new organism enters upon its career with only *two* flagella and the normal organism is possessed of four. But in a few minutes, three or four at most, the full complement were always there. How they were acquired it was the work of months to discover, but at last the mystery was solved. The newly-fissioned form darted irregularly and rapidly for a brief space, then fixed itself to the floor or to a rigid object by the ends of its flagella, and, with its body motionless, an intense vibratory action was set up along the entire length of these exquisite fibres. Rapidly the ends split, one half being in each fibre set free, and the other remaining fixed, and in 130 seconds each entire flagellum was divided into a perfect pair.

Now the amœboid state is a notable phenomenon throughout the monads as precursive of striking change. It appears to subserve the purpose of the more facile acquisition and digestion of food at a crisis. And this augmented the difficulty of discovering further change; and only persistent effort enabled us to discover that with comparative rareness there appeared a form in an amœboid state that was unique. It was a condition chiefly confined to the caudal end, the sarcode having become diffluent, hyaline, and intensely rapid in the protrusion and retraction of its substance, while the nuclear body becomes enormously enlarged. These never appear alone; forms in a like condition are diffused throughout the fluid, and may swim in this state for hours. Meanwhile, the diffluence causes a spreading and flattening of the sarcode, and swimming gives place to creeping, while the flagella violently lash. In this condition two forms meet by apparent accident, the protrusions touch, and instant fusion supervenes. In the course of a few

seconds there is no disconnected sarcode visible, and in five to seven minutes the organism is a union of two of the organisms, the swimming being again resumed, the flagella acting in apparent concert. This may continue for a short time, when movement begins to flag and then ceases. Meanwhile, the bodies close together, and the eyenots or vacuoles melt together, the two nuclei become one and disappear, and in eighteen hours the entire body of "either has melted into other," and a motionless, and for a time irregular, sac is left. This now becomes smooth, spherical, and tight, being fixed and motionless. This is a typical process; but the mingled weariness and pleasure realised in following such a form without a break through all the varied changes into this condition is not easily expressed.

But now the utmost power of lenses, the most delicate adjustment of light, and the keenest powers of eyesight and attention must do the rest. Before the end of six hours the delicate glossy sac opens gently at one place, then there streams out a glairy fluid densely packed with semi-opaque granules, just fairly visible when their area was increased six millions of times, and this continued until the whole sac was empty and its entire contents diffused. To follow with our utmost powers these exquisite specks was an unspeakable pleasure, a group seen to roll from the sac, when nearly empty, were fixed and never left. They soon palpably changed by apparent swelling or growth, but were perfectly inactive; but at the end of three hours a beaked appearance was presented. Rapid growth set in, and at the end of another hour, how has entirely baffled us, they acquired flagella and swam freely; in thirty-five minutes more they possessed a nucleus and rapidly developed, until at the end of nine hours after emission a sporule was followed to the parent condition and left in the act of fission. In this way, with what difficulties I need not weary you, a complete life-cycle was made out.

And now I will invite your attention to the developmental history of the *most minute* of the six forms we studied. In form it is a long oval, it is without visible structure or differentiation within, and is possessed of only a single flagellum. Its utmost length is the 5000th of an inch. Its motion is continuous in a straight line, and not intensely rapid, nor greatly varied, being wholly wanting in curves and dartings. The copiousness of its increase was, even to our accustomed eyes, remarkable in the extreme, but the reason was discovered with comparative ease. Its fission was not a division into two but into many. The first indication of its approach in following this delicate form was the assumption rapidly of a rounder shape. Then followed an amœboid and uncertain form, with an increased intensity of action which lasted a few moments when lassitude supervened, then perfect stillness of the body, which is now globular in form, while the flagellum feebly lashed, and then fell upon and fused with the substance of the sarcode. And the result is a solid, flattened, homogeneous ball of living jelly.

To properly study this in its further changes, a power of from three to four thousand diameters must be used, and with this I know of few things in the whole range of minute beauty more beautiful than the effect of what is seen. In the perfectly motionless flattened sphere, without the shimmer of premonition and with inconceivable suddenness, a white cross smites itself, as it were, through the sarcode. Then another with equal suddenness at right angles, and while with admiration and amazement one for the first time is realising the shining radii, an invisible energy seizes the tiny speck, and fixing its centre, twists its entire circumference, and endows it with a turbined aspect. From that moment intense interior activity became manifest. Now the sarcode was, as it were, kneading its own substance, and again an inner whirling motion was visible, reminding one of the rush of water round the interior of a hollow sphere on its way to a jet or fountain. Deep fissures or indentions showed themselves all over the sphere; and then at the end of ten or more minutes all interior action ceased, and the sphere had segmented into a coiled mass. There was no trace of an investing membrane; the constituent parts were related to each other simply as the two separating parts of an ordinary fission; and they now commenced a quick, writhing motion like a knot of eels, and then, in the course of from seven to thirty minutes separated, and fully endowed with flagella swam freely away, minute but perfect forms, which by the rapid absorption of pabulum attained speedily to the parent size.

It is characteristic of this group of organic forms that multiplication by self-division is the common and continuous method of increase. The other and essential method was comparatively rare and always obscure. In this instance, on the first occasion the continuous observation of the same "field" for five days failed to disclose to us any other method of increase but this multiple-fission, and it was only the intense suggestiveness of past experience that kept us still alert and prevented us from inferring that it was the *only* method. But eventually we perceived that while this was the prevailing phenomenon, there were scattered amongst the others forms of the same monad *larger* than the rest, and with a singular granular aspect towards the flagellate end. It may be easily contrasted with the normal or ordinary form. Now by doggedly following one of these through all its wanderings a wholly new phase in the morphology of the creature was revealed. This roughened or granular form seized upon and fastened itself to a form in the ordinary condition. The two swam freely together, both flagella being in action, but it was shortly palpable that the larger one was absorbing the lesser. The flagellum of the smaller one at length moved slower, then sluggishly, then fell upon the sarcode, which rapidly diminished, while the bigger form expanded and became vividly active until the two bodies had actually fused into one. After this its activity diminished, in a few minutes the body became quite still, leaving only a feeble motion in the flagellum, which soon fell upon the body-substance and was lost. All that was left now was a still spheroidal glossy speck, tinted with a brownish yellow. A peculiarity of this monad is the extreme uncertainty of the length of time which may elapse before even the most delicate change in this sac is visible. Its absolute stillness may continue for ten or more hours. During this time it is absolutely inert; but at last the sac —for such it is—opens gently, and there is poured out a brownish glairy fluid. At first the stream is small, but at length its flow enlarges the rift in the cyst, and the cloudy volume of its contents rolls out, and the hyaline film that inclosed it is all that is left.

The nature of the outflow was like that produced by the pouring of strong spirit into water. But no power that we could employ was capable of detecting a *granule* in it. To our most delicate manipulation of light, our finest optical appliances, and our most riveted attention, it was a homogeneous fluid and nothing more This for a while baffled and disturbed us. It lured us off the scent. We inferred that it might possibly be a fertilising fluid, and that we must look in other directions for the issue. But this was fruitless, and we were driven again to the old point, and having once more obtained the emitted fluid, determined to fix a lens magnifying 5000 diameters upon a clear space over which the fluid had rolled, and near to the exhausted sac, and ply our old trade of *watching*-unbroken observation.

The result was a reward indeed. At first the space was clear and white, but in the course of a hundred minutes there came suddenly into view the minutest conceivable specks. I can only compare the coming of these to the growth of the stars in a starless space upon the eye of an intense watcher in a summer twilight. You knew but a few minutes since a star was not visible there, and now there is no mistaking its pale beauty. It was so with these inexpressibly minute sporules; they were not there a short time since, but they grew large enough for our optical aids to reveal them and there they were. Such a field after one hour's watching I present to you. And here I would remark that these delicate specks were unlike any which we saw emerge directly from the sac as granules. In that condition they were always semi-opaque, but here they were transparent, and a brown yellow, the condition always sequent upon a certain measure of growth.

To follow these without the loss of an instant's vision was pleasure of the highest kind. In an hour and ten minutes from their first discovery they had grown to oval points. In one hour more the specks had become beaked and long. And this pointed end was universally the end from which the flagellum emerged. With the flagellum comes motion, and with that abundant pabulum, and therefore rapid growth. But when motion is attained we are compelled to abandon the mass and follow one in all its impetuous travels in its little world; and by doing so we are enabled to follow the developed speck into the parent condition and size, and not to leave it until it had, like its predecessors, entered on and completed its wonderful self-division by fission.

It becomes then clearly manifest that these organisms, lowly and little as they are, arise in fertilised parental products. There is no more caprice in their mode of origin, than in that of a crustacean or a bird. Their minuteness, enormous abundance, and universal distribution, is the explanation of their rapid and

practically ubiquitous appearance in a germinating and adult condition. The presence of putrefiable or putrescent matter determines at once the germination of the always-present spore. But a new question arises. These spores are definite products. In the face of some experimental facts one was tempted to inquire, have these spores any capacity to resist heat greater than the adults? It was not easy to determine this question. But we at length were enabled to isolate the germs of seven separate forms, and by means of delicate apparatus, and some twelve months of research, to place each spore sac in an apparatus so constructed that it could be raised to successive temperatures, and without any change of conditions examined on the stage of the microscope.

In this way we reached successive temperatures higher and higher until the death point—the point beyond which no subsequent germination ever occurred—was reached in regard to *each* organism. The result was striking. The normal death point for the adult was 140° F. One of the monads emitted from its sac minute mobile specks—evidently living bodies—which rapidly grew. These we always destroyed at a temperature of 180° F. Three of the sacs emitted spores that germinated at every temperature under 250° F. Two more only had their power of germination destroyed at 260° F. And one, the least of all the monad forms, in a heat partially fluid and partially dry, at all points up to 300° F. But if wholly in fluid it was destroyed at the point of 290° F. The average being that the power of heat resistance in the spore was to that of the adult as 11 to 6. From this it is clear that we dare not infer spontaneous generation after heat until we know the life-history of the organism.

In proof of this I close with a practical case. A trenchant and resolute advocate of the origin of living forms *de novo*, has published what he considers a crucial illustration in support of his case. He took a strong infusion of common cress, placed it in a flask, boiled it, and, whilst boiling, hermetically sealed it. He then heated it up in a digester to 270° F. It was kept for nine weeks and then opened, and, in his own language, on microscopical examination of the earliest drop "there appeared more than a dozen very active monads." He has fortunately measured and roughly drawn these. A facsimile of his drawing is here. He says that they were possessed of a rapidly moving lash, and that there were other forms without tails, which he assumed were developmental stages of the form. This is nothing less than the monad whose life-history I gave you last. My drawings, magnified 2500 diams., of the active organism and the developing sac, are here.

Now this experimenter says that he took these monads and heated them to a temperature of about 140° F., and they were all absolutely killed. This is accurately our experience. But he says these monads arose in a closed flask, the fluid of which had been heated up to 270° F. Therefore, since they are killed at 140° F., and arose in a fluid after being heated to 270° F., they must have arisen *de novo!* But the truth is that this is the monad whose spore only loses its power to germinate at a temperature (in fluid) of 290°, that is to say, 20° F. higher than the heat to which, in this experiment, they had been subjected. And therefore the facts compel the deduction that these monads in the cress arose, not by a change of dead matter into living, but that they germinated naturally from the parental spore which the heat employed had been incompetent to injure. Then we conclude with a definite issue, viz., by experiment it is established that living forms do not now arise in dead matter. And by study of the forms themselves it is proved that, like all the more complex forms above them, they arise in parental products. The law is as ever, only that which is living can give origin to that which lives.

WHIRLWINDS AND WATERSPOUTS[1]

WHIRLWINDS, whether on sea or on land, have their characters in great part alike. For simplicity it will be convenient to begin by taking up only the case of whirlwinds on sea, as thus the necessity for alternative expressions to suit both cases, that of sea and that of land, will be avoided.

It may be accepted as a fact sufficiently established, both by dynamic theory and by barometric observations, that at the sea-level the pressure of the air is less in the neighbourhood of the axis of whirl than it is at places farther out from the axis, though within the region of the whirl. The apocentric force (centrifugal force) of the rapidly-revolving air resists the inward pulsive tendency of the greater outer than inner pressure. But close over the surface of the sea there exists necessarily a lamina of air greatly deadened as to the whirling motion by fluid friction, or resistance, against the surface of the sea; and all the more so because of that surface being ruffled into waves and often broken up into spray. This frictionally-deadened lamina exerts, because of its diminished whirl speed, less apocentric force than the quicker-revolving air above it, and so is incapable of resisting the inward pulsive tendency of the greater outer than inner pressure already mentioned. Hence, while rushing round in its whirl, the air of that lamina must also be flowing in centreward.

The influx of air so arriving at the central region cannot remain there continually accumulating; it is not annihilated, and it certainly does not escape downwards through the sea. There is no outlet for it except upwards, and as a rising central core it departs from that place. This is one way of thinking out some of the conditions of the complex set of actions under contemplation; but there is much more yet to be considered.

Hitherto, in the present paper, nothing has been said as to the cause or mode of origin of the diminished barometric pressure which, during the existence of the whirlwind, does actually exist in the central region. Often in writings on this subject the notion has been set forth that the diminished pressure is caused by the rapid gyratory motion of the whirling air; but, were we to accept that view, we would have still to ask, How does the remarkably rapid whirling motion receive its own origin? The reply must be that the view so offered is erroneous; and that, in general, a diminished pressure existing at some particular region is the cause rather than the effect of the rapid whirling motion; though in some respects indeed these two conditions can be regarded as being mutually causes and effects, each being essential to the maintenance of the other, while there are also some further promoting causes or conditions not as yet here mentioned.

It seems indubitably to be the truth that ordinarily for the genesis of a whirlwind the two chief promoting conditions are: firstly, a region of diminished barometric pressure, this diminution of pressure being, it may be presumed, due to rarefaction of the atmosphere over that region by heat, and sometimes, further, by its condition as to included watery vapour; and, secondly, a previously existing revolutional motion, or differential horizontal motion, of the surrounding air, such revolutional or differential motion being not necessarily of high velocity at any part.

The supposed accumulation of air rarefied by heat or otherwise, for producing the abatement of pressure may, the author supposes, in some cases extend upwards throughout the whole depth of the atmosphere; and in some cases may be in the form of a lower warm lamina which somehow may have been overflowed or covered by colder air above, through which, or into which, it will tend to ascend: or the lower lamina may in some cases be warmed in any of several ways, and so may get a tendency to rise up through the colder superincumbent atmosphere. On this part of the subject the author believes there is much scope for further researches and advancements both observational and considerational;—that is to say, by encouragement of a spirit towards accurate observation; and by collection and scrutiny of observed facts and appearances; and by careful theoretical consideration founded on observational results or suppositions.

To the author it seems probable that the great cyclones may have their region of rarefied air extending up quite to the top of the atmosphere; while often whirlwinds of smaller kinds, many of the little dust whirlwinds, for instance, which are frequently to be seen, may terminate, or gradually die out, at top in a layer or bed of the atmosphere different in its conditions, both as to temperature and as to original motion, from the lower layer in which the whirlwind has been generated. In many such cases the upper air may probably be cooler than the lower air in which the whirlwind originates.

On the subject of the actions going on at the upper parts or upper ends of whirlwind cores in most cases, the author feels that he is able to offer at present little more than suggestions and speculative conjectures. In very many descriptions of the appearances presented by those whirlwinds with visible revolving cores, which are called waterspouts, it is told that the first appearance of th

[1] Paper by James Thomson, LL.D., D.Sc., Professor of Civil Engineering and Mechanics in the University of Glasgow, read in Section A, at the British Association meeting at Montreal, on Monday, September 1.

so-called waterspout consists in the rapid shooting down from a dense cloud of a black cloudy streak, seemingly tortuously revolving and swaying more or less sidewise. This is said rapidly to prolong itself downwards till it meets the surface of the sea; and the water of the sea is often imagined and described as rising up bodily, or as being drawn up, into the partial vacuum or central columnar place of diminished pressure. The frequently entertained notion—a notion which has even made its way into writings by men of science and of authority in meteorology—that the water of the sea is sucked up as a continuous liquid column in the centre of waterspout whirlwinds, is by some writers and thinkers repudiated as being only a popular fallacy, and it is affirmed that it is only the spray from the broken waves that is carried up. In this denial of the supposition of the water being sucked up as a continuous liquid column the author entirely agrees, and he agrees in the opinion that spray or spindrift from the sea set into violent commotion by the whirlwind is carried up in a central ascending columnar core of air.

On the other hand, the commonly-alleged inception of the visible waterspout phenomena, in a descending, tortuously-revolving, and laterally-bending or swaying cloudy spindle protruding from a cloud, the author supposes to be so well accredited by numerous testimonies that it must be seriously taken into account in the development of any true theory and explanation of the physical conditions and actions involved. He ventures to hazard a suggestion at present—perhaps a very crude and rash one. It is that the rising central core may perhaps, in virtue of its whirling motion and centrifugal tendency, afford admission for the cloudy stratum to penetrate down as an inner core within that revolving ascending core now itself become tubular. The cloudy stratum may be supposed not originally to have been endowed with the revolutional motion or differential horizontal motion with which the lower stratum of thermally expanded air has been assumed to be originally endowed. The upper stratum of air from which the cloudy spindle core is here taken to protrude down into the tubular funnel is not to be supposed to be cold enough to tend to sink by mere gravity. Though it were warm enough to allow of its floating freely on the thermally expanded air below, it could still be sucked down into the centre of the revolving ascending core of the whirlwind.

Not to proceed further on this occasion with attempts towards explanation of the difficult subject of the actions at the upper ends of waterspout whirlwinds, the author wishes to have it understood that his main object in proceeding to prepare the present paper was to put forward clearly the theory he has given as to influx at the bottom in consequence of abatement of whirl in the lamina close to the sea-surface by frictional resistance there.

Addendum.—A few brief explanations and references will now be added to assist in the understanding of some of the principles assumed in what has been already said. It is to be clearly understood that, in a whirling fluid, even if the velocity of the whirling motion be very small at great distances from the axis, if the fluid be impelled inwards by forces directed towards the axis, the absolute velocity will greatly increase with diminution of distance from the axis. Thus in the *whirlpool of free mobility*, in which the particles are perfectly free to move outward or inward, the velocities of the particles are inversely proportional to the distances from the axis, the fluid being understood to be inviscid or frictionless. On this subject reference may be made to a paper by the author on "Whirling Fluids," published in the British Association volume for the Belfast Meeting, 1852. Again, as to the inward flow caused in a frictionally retarded bottom lamina of a whirlwind or whirlpool with vertical axis, by the frictional retardation from the bottom on which the whirling fluid rests, reference may be made to a paper by the author, "On the Grand Currents of Atmospheric Circulation" in the British Association Report, Dublin Meeting 1857, part ii. p. 38. On another case of the manifestation of the same principle, reference may be made to a paper by the author in the *Proceedings* of the Royal Society for May 1876, in respect to the "Flow of Water round Bends in Rivers, &c.," with reference to the effects of frictional resistance from the channel in the bends; and to another paper by him, on the same subject in the *Proceedings* of the Institution of Mechanical Engineers (August 1879, p. 456), where the inward flow is explained as experimentally exhibited.

Postscript of date August 16.—Prof. James Thomson wishes now to offer in continuation of his paper on "Whirlwinds and Waterspouts," despatched two days ago for Montreal the following postscript, which will extend the considerations there already put forward, and will tend to modify or amend some of them; but will leave unchanged the theory as to influx of the bottom lamina of the whirlwind towards the central region in consequence of the frictional resistance offered by the surface of the sea to the air whirling in close contiguity upon that surface.

He wishes to put forward the question as to whether it may not be possible, in some cases of whirlwinds, for the barometric pressure in the central or axial region to become abated through the combined influences of rarefaction by heat (increased, perhaps, by conditions as to included moisture) on the one hand, and the whirling motion on the other hand, very much beyond the abatement that could be due to heat, or heat and moisture, alone, without the whirling motion. He thinks it very likely that in great whirlwinds, including those which produce the remarkable phenomena called waterspouts, it may be impossible for the whirling action to be confined to the lower region of the atmosphere; but that, even if commenced there, it would speedily be propagated to the top. It seems also not unlikely, and in some trains of thought it comes to appear very probable, that the whirling fluid, ascending by its levity, would drive outwards from above it all other air endowed with less whirling energy, and would be continually clearing away upwards and outwards the less energetic axial core which enters from below, and any, if such there be, that has entered from above. He is unable at present to offer much in further elucidation (possibly it might only prove to be in further involvement) of this very difficult subject. He thinks the question should at least be kept open as to whether the whirling and scouring action may not go forward growing more and more intense, promoted always by energies from the thermal sources which have produced differences of temperature and moisture in different parts of the atmosphere, and that thus a much nearer approach to vacuum in the centre may be caused than would be due merely to the levity of the superincumbent air if not whirling.

He also wishes to suggest that the dark and often frightful cloud usually seen in the early stages of whirlwinds and waterspouts, and the dark columnar revolving core often seen apparently protruding downwards from the cloud, may be due to precipitation of moisture into the condition of fog or cloud, on account of abatement of pressure by ascension in level, and environment with whirling air, which by its centrifugal tendency acts in protecting the axial region from the pressure inwards of the surrounding atmosphere.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Dr. Besant and Mr. C. H. Prior are appointed Moderators, and Messrs. C. Graham and A. J. C. Allen Examiners, in the Mathematical Tripos for the year beginning May 1, 1885.

The following Natural Science Examiners have been appointed:—Physics: Prof. A. Schuster and Mr. W. N. Shaw; Chemistry: Messrs. A. Scott and M. Pattison Muir; Mineralogy: Prof. Lewis and Mr. H. P. Gurney; Geology: Messrs. R. D. Roberts and J. J. H. Teall; Botany: Messrs. F. Darwin and H. M. Ward; Zoology: Prof. A. M. Marshall and Mr. A. Sedgwick; Human Anatomy: Prof. A. Macalister and Mr. A. Hill; Physiology: Prof. Michael Foster and Mr. J. N. Langley.

St. John's College offers for competition in December next a large number of Open Scholarships, Exhibitions, and Sizarships. Natural Science is one of the subjects which, taken singly, may lead to election to any of these. The subjects are in general those of the Natural Sciences Tripos; but every candidate in Natural Science must show a competent knowledge of two at least of the following subjects:—Physics, Chemistry, and Biology, all in an elementary sense. A candidate, however, may be elected on the ground of special proficiency in any one of the subjects of examination. There will be both papers and practical work in all subjects. Further information may be obtained from the tutors.

Trinity College Examinations begin on December 11. Major and Minor Scholarships, Exhibitions, and Sizarships may be given for Natural Science. One Exhibition at least, of the value of 50*l*., will be given for Natural Science to a candidate not yet in residence at the University.

King's College offers an Exhibition of 60*l*. per annum for Natural Science: examination on December 11.

Emmanuel College holds its Entrance Scholarship Examination conjointly with Christ's and Sidney-Sussex Colleges. The subjects in Natural Science are Chemistry, Physics, Elementary Biology, and Geology and Mineralogy. In all branches of Natural Science there is a practical examination. The examinations will begin on January 6 next. A candidate for a Scholarship at one of the above Colleges may be elected to a Scholarship at either of the others in default of better qualified candidates.

Mr. Lea will lecture on Chemical Physiology this term at the New Museums.

Mr. Sedgwick has arranged for a repetition class in Elementary Biology in the Morphological Laboratory, to be superintended by Mr. Weldon.

OWENS COLLEGE, MANCHESTER.—At a recent meeting the Council, on the recommendation of the Senate, made the following appointments to the three vacant Berkeley Fellowships:—In Chemistry, Dr. L. Claisen, formerly First Assistant in Organic Chemistry to Prof. Kekulé of Bonn. In Zoology, Dr. John Beard, of the University of Freiburg, and formerly of Owens College. In Philosophy, Mr. W. E. Johnson, B.A., of King's College, Cambridge. The Berkeley Fellowships are for the encouragement of original research, and the holders are required to reside in Manchester during term time.

SCIENTIFIC SERIALS

Bulletins de la Société d'Anthropologie de Paris, tome vii. fasc. 2, 1884.—This number contains several more than usually interesting communications regarding French palæontological inquiry.—M. D'Acy's paper on the silex of the Chelles Station, which was begun in a previous number, shows that we must regard the Chelles deposits as belonging to two distinct formations: the old Quaternary, or true Chellean, containing remains of *Elephas antiquus* and *Rhinoceros merkii*, and the later Quaternary, or mousterian period, represented as usual by *Elephas primigenius*.—Baron de Baye communicates the discovery in the Neolithic caverns at Petit Morin (Marne) of transversely cut arrow-heads similar to those found in large quantities in Denmark, but hitherto undetected in France. They were intermixed with numerous ordinarily shaped arrow-heads, fragments of Neolithic pottery, and roughly-cut flints, and deposited in a cavity on the summit of a hill, while a vertebral bone (apparently of a badger), which was found in a grotto at a distance of 250 m. from the deposit, still retained a portion of a similarly shaped arrow-head.—M. Gustave Chauvet announced the discovery, in a tumulus on the right bank of the Charente, of a curiously ornamented bronze chariot, similar to those found in Mecklenburg and in Scandinavia. The tumulus, which is situated near Charroux (Vienne), and locally known as "le Gros-Guignon," contained a vaulted recess in which the body had rested, and on either side of which lay wheels with detached ornaments, as circles and spheres, and bronze and iron nails, together with two urns undoubtedly Gallic.—M. Nicaise reported the discovery of another chariot-bier in a tumulus at Septaulx (Marne), on which the body had been laid. In front of the right wheel lay the skeleton of a boar, between whose ribs a long knife was embedded. To this report the writer has added many interesting details in regard to several funeral chariots found in other parts of Marne, more especially in the Gallic cemetery of Varilles, where three skeletons (one adult and two children) had been interred in the same chariot. The weapons, horse-bits, bronze rings, &c., inclosed in these tumuli indicate their Gallic origin.—On the sepulchral grotto of Rousson, near Alais, by M. Charvet. This cave, which was opened in 1883, was found to contain a large number of skulls, mostly dolichocephalic, together with other human bones, and pins and beads of a metal regarded by French palæontologists as copper rather than bronze, and similar to that of various objects found in the Baume des Morts Cavern of Durfort, first explored in 1869, and regarded as belonging to a mixed Celto-Ligurian race.—On a series of explorations at Plouhinec, by M. Gaillard. Four tumuli opened in March 1884 contained cinerary urns, four human skulls, and other bones, flint lance- and arrow-heads, and broken pottery.—A communication by M. Kerckhoffs concerning the lacustrine station lately brought to light near the alluvial beds, in which the notable Maestricht jaw was discovered in 1823. The recent explorations of this interesting site have been conducted by M. Ubaghs, who has found a well-preserved dolichocephalic cranium, together with the bones of *Bos primigenius*, the horse, stag, beaver, dog, &c., with bone instruments, remains of coarse pottery, &c.—On human sacrifices and anthropophagy among the Vaudous or serpent-worshippers of Haiti, by M. Dehoux.—On the settlements of the Canadian Redskins, and the fluctuation in their numbers, by M. Petitot. The author considers that the solar and demon worship, and the chief social institutions of the Sioux, Hurons, and other North American tribes indicate their affinity with the Dravidian races of India.—The report of a discussion raised by M. Beauregard on the correctness of his views regarding the Dardous, which had been called in question by M. de Ujfalvy.—On the Cachmiris and Pandits, by M. de Ujfalvy. The former he regards as a mixed Mongol and Aryan race, while in the latter he believes we have the representatives of a primitive North-West Indian Aryan type.—On the pretended Eastern origin of the Algonquins, by M. Petitot; and on the diffusion of analogous myths in different lands, by M. Luys.—On dynamometric errors, by Dr. Manouvrier, having special reference to the inexactness of instruments, and the discrepancies between the modes of gradation observed by different instrument-makers.—On the ethnographic researches of M. Quesde in the Antilles, by M. Hamy. The presence of cut flints, although there are no indications of any siliceous rock-formations, points to primitive commercial relations with the mainland.—On the methods of measuring the circumference of the head, by M. le Bon.—A new classification of the pelvis considered from an obstetric point of view, and with special reference to racial distinctions, by Dr. Verrier.—On the traditions and tribal divisions of the Somalis, by M. Bardey. Their legends include one in which Abel is represented as the black and evil brother, while Kahil is white-skinned and good, while the people profess to derive their descent from two men miraculously saved with their wives from an inundation which ingulfed all the inhabitants of the lands near the Mount Taizz, sixty miles east of Mocha, on the summit of which they remained till the waters subsided.

Bulletin de l'Académie Royale de Belgique, July 5.—Monograph on the central nervous system of adult Ascidians, and its relations to that of the Urodele larvæ (four plates), by MM. Ed. Van Beneden and Ch. Julin.—Note on the calculation of averages; application of a new principle of probabilities, by E. Catalan.—Remarks on the ventral disk of the sea-snail, *Liparis barbatus* (one plate), by Maurice Stuckens.—On the respiration of bats during the period of hibernation, by E. Delsaux.—Anatomy of the cephalic kidney of the larva of Polygordius; a contribution to the history of the excreting apparatus of worms, by Julien Fraipont.—On the central and surface nervous systems of the Archiannelids (Protodrilus, Polygordius); a contribution to the history of the origin of the nervous system in these worms, by Julien Fraipont.—On a theorem in mechanics applicable to systems whose movement is periodical, by E. Ronkar.

August 2.—Note on two remarkable experiments in capillary attraction, by G. van der Mensbrugghe.—On the theory of elliptical functions, by P. Mansion.—On the remainder in Taylor's formula, and on the binomial theory, by P. Mansion.—Chemical analysis of a rich phosphate recently discovered in the neighbourhood of Havré near Mons, by C. Blas.—On the conductivity of gaseous bodies for heat, by E. Ronkar.—On the theoretic relations between the coefficients of expansion, the internal heat of vaporisation, and the specific heats of bodies in the liquid and gaseous states, by P. de Heen.—Description of a new apparatus for determining the coefficient of diffusion of salts in solution, and the variations experienced by this quantity according to the temperature, by P. de Heen.—On the generation of certain surfaces by means of quadrilinear groups, by C. Le Page.—Researches on the production of cyanhydric acid in the vegetable kingdom, by A. Jorissen.—Historic note on Stephen Dushan, Emperor of Servia, and the Balkan Peninsula in the fourteenth century, by Emile de Borchgrave.—Discourse pronounced at the obsequies of M. Alexandre Pinchart, by M. Silngeneyer.

SOCIETIES AND ACADEMIES

LONDON

Mineralogical Society, October 21.—Anniversary meeting.—The Rev. Prof. Bonney, F.R.S., President, in the chair.—The Hon. Sec., Mr. R. H. Scott, read the Report of the Council.—The scrutineers reported that the following were elected Officers and Council:—President: Rev. Prof. T. G. Bonney, D.Sc., LL.D., F.R.S., F.S.A., Pres.G.S.; Vice-Presidents: Rev. S. Haughton, M.D., F.R.S., W. H. Hudle-

ston, J.P., F.R.S.; Council: T. W. Danby, M.A., F.G.S., J. J. Dobbie, D.Sc., L. Fletcher, M.A., Prof. W. J. Lewis, M.A.; Treasurer: R. P. Greg, F.G.S., &c.; General Secretary: H. Scott, M.A., F.R.S.; Foreign Secretary: T. Davies, F.G.S.—The President delivered an address, in which he congratulated the Society on the satisfactory character of the Report presented by the Council. This mentioned three topics, all congratulation: First, it announced that the fusion of the Society with the Crystallological, thanks to the good offices of the Honorary Secretary, had been accomplished. Next, it announced that the finances of the Society, which three years ago were in a condition far from satisfactory, were now restored to a healthy tone. Lastly, it spoke of the great success which had attended the meeting held in Edinburgh last June. He trusted that in future one of the meetings of the Society would always be held in Scotland. He then proceeded to criticise two defects which in his opinion existed in systematic mineralogy as set forth by many authors. To some extent these were questions of nomenclature, but in his opinion they involved questions of principle. The one was the extreme proneness of mineralogists to give distinctive names to slight and often very ill-defined varieties of existing species, thus leading students to mental habits of dissociation rather than of correlation. The other at first sight appeared exactly the converse of this, namely, the laxity with which certain substances were classed as minerals. For instance, obsidian, pitchstone, &c., were often placed in text-books under the head of orthoclase feldspar, but they could not be brought under any received definition of a mineral. He pointed out how, in consequence as he believed, of the defective habits of reasoning thus engendered, the contributions to petrology, even of skilled mineralogists, were sometimes of little value.—Mr. R. H. Solly read a paper on five specimens of lilac calcite from Tankerville Mine, Salop.—Mr. Semmons read some further notes on "Euargite."—M. Guyot de Grandmaison exhibited a very fine crystal of "Parisite."—Mr. Rudler and Mr. T. Davies also exhibited several interesting minerals.

SYDNEY

Linnean Society of New South Wales, August 27.—C. S. Wilkinson, F.G.S., F.L.S., President, in the chair.—Dr. Otto Finsch was introduced as a visitor.—The President announced that, at the last meeting of the Council, F. Jeffrey Bell, M.A., Professor of Comparative Anatomy at King's College, London, had been elected a Corresponding Member of the Society.—The following papers were read:—New fishes in the Queensland Museum, No. IV., by Charles W. De Vis, M.A. The families Gobiidæ and Blenniidæ form the subject of this paper; thirty-one new species are described.—Notes on the eyes of deep-sea fishes, by Dr. von Lendenfeld. In this paper the author combats the views expressed by Mr. Archer of New Zealand, in opposition to his (Dr. Lendenfeld's) theory as regards the eyes of *Lepidotus caudatus*.—The insects of the Maclay coast, by William Macleay, F.L.S. The "Maclay Coast," so named after the distinguished traveller Baron N. de Mikluho-Maclay, who resided there for nearly three years, is a portion of Astrolabe Bay, on the North Coast of New Guinea, and the insects collected there, and now enumerated, are of interest as being the only ones ever received from that portion of the island. The collection is very small, and the species have been for the most part previously described from Dorey and New Ireland.—Notes on the zoology of the Maclay Coast, New Guinea: (i.) on a new sub-genus of *Peramelidæ*, by N. de Mikluho-Maclay. Baron Maclay gives to the bandicoot here described the name of *Brachymelis garagassi*. The sub-genus is characterised by having four upper incisors instead of five (in which character it resembles *Perameles doreyanus*, Quoy and Gaimard, and *P. cockerelli*, Ramsay), in having very short limbs and in having the hair on the back very bristly. A stuffed specimen was exhibited, which Dr. Otto Finsch pronounced to be distinct from his New Britain species.—Descriptions of Australian Micro-lepidoptera, No. XI., by E. Meyrick, B.A. Mr. Meyrick continues the Œcophoridæ, describing in detail over 100 species, bringing the number of that family up to nearly 400.—Critical list of Mollusca from the north-west coast of Australia, by John Brazier, C.M.Z.S., &c. Fifty species are here enumerated, with the geographical range and synonymy of each correctly defined.—Synonymy of some New Guinea land shells, by John Brazier, C.M.Z.S., &c. Mr. Brazier accompanied the reading of this paper with the exhibition of the following species of Helicidæ:—*Helix broadbenti*, Braz.; *H.* (*Obba*) *goldiei*, Braz.; *H.* (*Geotrochus*) *zeno*, Braz.; *H.* (*Geotrochus*) *tapperonii*, Smith; *H.* (*Geotrochus*) *tayloriana*, Ad. and Reeve; *H.* (*Sphærospira*) *gerrardi*, E. A. Smith; *H.* (*Planispira*) *corniculum*, Hombr. and Jacq.; *Nanina* (*Xesta*) *citrina*, Linn.—The time of the Glacial period in New Zealand, by R. von Lendenfeld, Ph.D. The results of the author's survey in the New Zealand Alps, partly corroborating and partly extending the results of Dr. von Haast's surveys, showed that the present glaciers are as large and extend down as far as those in Norway, where the mean annual temperature is 3° C., whilst in New Zealand it is 11° C. The greater expanse of water in the southern hemisphere and the consequently greater amount of humidity in the air, and more copious rain and snowfall are considered to be the cause of this. The sounds in the south-west coast are similar to the fjords in Norway, and the alluvial deposits at their upper ends are small. Scooped out originally by flowing water, these sounds remained unchanged during the period of subsidence of the land, and were not filled up with debris, because large glaciers occupied them during that time. As soon as these glaciers disappeared, the formation of the alluvial deposits commenced, and from the fact that the latter are small and increasing rapidly in size from year to year, the author considers that the Glacial period in New Zealand must have been very recent.—List of papers and works relating to the mammalian orders Marsupialia and Monotremata, by J. J. Fletcher, M.A., B.Sc. The aim of this catalogue, which contains the titles and references of several hundred papers, &c., is to do for the student of these two interesting and peculiarly Australian orders of the Mammalia what Etheridge and Jack's Catalogue has done for the student of Australian geology. It includes all papers dealing with the anatomy of these groups, all descriptions of new species since the publication of Gould's work, and a few papers on palæontology, omitted from Etheridge and Jack's Catalogue, together with a few published since that appeared. Mr. Fletcher exhibited a number of the rarer papers enumerated in the list.—On two new birds from the Austro-Malayan region, by E. P. Ramsay, F.R.S.E. The species here described are: (1) *Pitta finschii*, sp. nov., allied to *Pitta mackloti*, but distinct in having no red nape patch, and the whole of the upper surface except the head blue, instead of green. (2) *Halcyon albonotata*, sp. nov. This species comes under the sub-genus *Cyanalcyon*; it is allied to *Halcyon macleayi* and *H. diops*, but differs from all in having the whole of the back and upper tail-coverts white.

PARIS

Academy of Sciences, October 20.—M. Rolland, President, in the chair.—Note on the conditions of the existence of equal roots in Hamilton's equation of the second degree, and on a general method of resolving a unilateral equation of any degree in matrices of any order, by Prof. Sylvester.—On the alkaline hydrates, third memoir: hydrates of potassa and soda, by M. E. J. Maumené.—Note on the effects of tar-wash on vines attacked by Phylloxera, by M. Balbiani. A decisive experiment recently made by the author on a young plantation near Montpellier showed the possibility of utterly destroying the winter eggs deposited in any given vineyard by the application of a coal-tar wash. But all the plants subjected to this treatment arrived at maturity a fortnight or three weeks later than any others. This result was attributed to the obstacle opposed to the evaporation by the coating thus formed round the stem of the plant.—Occultation of stars by the moon observed at Toulouse during the recent lunar eclipse, by M. Baillaud.—Observations of the same eclipse made at the Observatory of Bordeaux, by MM. Doublet, Flamme, and Courty. These observations, made under rather favourable atmospheric conditions with the 8-inch and 14-inch equatorials, were directed chiefly to some of the stars indicated in M. Struve's list. It was ascertained that none of the stars disappeared at the exact moment of its occultation, almost implying that the edge of the lunar disk is transparent.—Observations of Wolf's comet (1884), made with the meridian circle of the Observatory of Bordeaux, by M. Courty. The brightness of the comet appears to have slightly increased since the first observations, although the nucleus still remains comparable to a star of the ninth magnitude.—Observations of the new planet 244, made at the Observatory of Algiers (0·50 m. telescope), by M. Rambaud.—Observations of the late total eclipse of the moon at Orgères (Eure-et-Loir), M. Edm. Lescarbault.—Note on the determination of the orbits of heavenly bodies by three observations, by M. R. Radau.—Observations made on the intensity of terrestrial magnetism in European Russia, by Gen. A. de Tillo.—Note on the elementary force of solar induction, whose periodical duration

is a mean day, by M. Quet.—On the disruptive discharges of Holtz's electric machine, by M. l'Abbé Maze.—On the trifluoride of phosphorus, by M. H. Moissan. — On the results obtained from the application of potash manures to certain hitherto unreclaimed lands in Brittany, by M. G. Lechartier.—Fresh comparative experiments with the rabbit and guinea-pig inoculated with the virus of human scrofula and tuberculosis, by M. S. Arloing.—Note on the character and constitution of the light fleecy clouds present in the upper regions of the terrestrial atmosphere, by M. A. Badoureau. In these regions the author assumes that the temperature falls to absolute zero, and although the pressure is also reduced to zero, it seems probable that the carbonic acid, nitrogen, and oxygen are here successively condensed into clouds analogous to those formed lower down by vapour. To the clouds formed by these elements might be attributed the phenomenal solar halos recently described by M. Cornu.

BERLIN

Meteorological Society, October 7.—Dr. Hellmann gave a short report of the proceedings of the annual meeting of the German Meteorological Society, which held its sitting at Magdeburg from September 18 to 22, simultaneously with that of the German Natural Science Association. Communications on the scientific inquiries and observations having been delivered in the Meteorological Section of the Natural Science Association, it was only matters connected with organisation which occupied the attention of the Meteorological Society, and the most important of the conclusions arrived at by them formed the substance of Dr. Hellmann's address.—Prof. Börnstein spoke on rain measurement, and, after a concise historical review of the more important observations of earlier times, on the dependence of the readings of rain-gauges on their position and exposure, and on the attempts made to explain that fact, he reported observations of his own which he had made for the purpose of testing the influence which, according to assertions by many *savants*, the wind exercised on the readings of rain-gauges. Mr. Nipher, as was known, had in 1878 proposed, as a counteractive to the influence of the wind, to surround the collecting cylinder of the rain-gauges with a protective funnel. Beside a Nipher rain-gauge of this construction Prof. Börnstein had set another rain-gauge which was surrounded with a reversed funnel, and must necessarily show the influence of the wind in increased measure. By a comparison of the measurements of these two gauges from January to July of this year, he ascertained that the latter regularly collected less rain than the former. The difference was greatest in the case of snow falling, less in the case of a drizzling rain, still less during an ordinary shower of rain, and least of all with a heavy downpour. On comparing the readings of the two rain-gauges, according to the strength of the winds prevailing at the times of the different rainfalls, it appeared that, when the strength of the wind was 0, the differences were least of all; greater differences appeared when the strength of the wind was 1, still greater when its strength was 2, and the greatest when it rose to 3. Winds of greater violence than 3 came too seldom to allow of correct determinations regarding their influence on the rain-gauges.—In connection with this address Dr. Hellmann stated that at the Prussian stations it was sought to abate the influence of the wind by placing the rain-gauges one metre above the ground, and surrounding them with a hedge one metre and a half in height and at a distance of two metres. He then explained several models of rain-gauges.—Prof. Förster reported several series of experiments on the measurement of heat carried out by the Normal Standard Commission under his direction. As a result of these investigations it appeared that the possible errors of even the best mercurial thermometers were very considerable. In the first place, the successive expansion of the glass, if repeatedly heated up to 100° C., might be very great, to the extent even of displacing the fixed points by several degrees. The amount of this change was dependent on the chemical composition of the glass. According to Herr Wiebe's measurements those were the worst glasses in this respect which were markedly rich in potassium and sodium, especially those containing equal quantities of these substances. Happily glass factories were beginning to take account of this circumstance in their supply of glasses for instruments of precision. The expansion coefficients of the glass, and the relation of the glass to the quicksilver expansion, was another source of error, producing important deviations from the readings of the gas thermometer. In the latter case, likewise, the chemical composition of the glass played a part which would require to be more particularly determined, and it was to be hoped that the investigations now in progress would soon settle the corrections imposed by that factor in the case. The gas thermometer was itself not absolutely trustworthy, as had been shown by the most recent experiments, which had demonstrated that all gases employed were more or less absorbed by the glass, and the more so the longer the gas remained in contact with the walls of the thermometer. That this absorption prejudicially affected the readings of the thermometer, if only to hundredths of a degree, had been already proved. Continued experiments with nitrogen and carbonic acid thermometers in vessels of glass and platinum-iridium would bring to light the corrections to be applied; these in conjunction with the other corrections would alone render the thermometer a true scientific instrument.—Dr. Kayser has photographed flashes of lightning, and obtained the ramified lightning-pictures now universally known. One flash, however, which he showed to the Society, was distinguished by the fact that it presented four unramified, irregularly undulatory lines running in exact parallels from top to bottom. These four lightning-lines must, by reason of their parallelism, have arisen simultaneously or immediately after one another in order that their discharges should have pursued the same lightning-track. The first flash was further distinguished by a series of light-layers attached to one side of it. Dr. Kayser was of opinion that a double discharge was here pictured, going and coming, the course of which had been displaced by a strong wind (thirty metres per second). The amount of the displacement could be approximately calculated, and so the time between the first and second discharge might be estimated to within some hundredths of a second.
